Fig. 140.1 Age-specific incidence of systemic sclerosis by race and sex. (Adapted with permission from Mayes MD, Lacey JV Jr, Beebe-Dimmer J, et al. Prevalence, incidence, survival, and disease characteristics of systemic sclerosis in a large U.S. population. *Arthritis Rheum* 2003;48:2246-55.)

Steen and coworkers¹⁴ reported that the age-specific incidence rate peaked between ages 45 and 54 in African American women and occurred in a slightly older group (age 55 to 65) in European American women. Diagnosis before age 15 was rare. In the 15- to 24-year age group, the incidence was very low, except among African American women, who showed an incidence of 21.2 per million; this was a significantly higher incidence than in European American women of the same age group (incidence ratio, 11.16; $P < .0001$). The incidence rate for African American men also peaked between the ages of 45 and 54, whereas the European American men showed an increase in annual incidence up to the age of 65.

Mayes and coworkers¹³ found very similar results, reporting that African American patients were significantly younger at the time of diagnosis compared with European American patients ($P < .001$). The peak incidence occurred between the ages of 45 and 54 for African American women, whereas the peak incidence among white women occurred in the 65- to 74-year age group. The peak incidence age for African American men was similar to that for African American women. Among European American men, incidence increased gradually until the age of 75 to 84 years. Fig. 140.1 shows the age-specific incidence of SSc by ethnicity and sex in this study. The observed differences in average age at diagnosis might be due to the increased occurrence of diffuse disease in the African American population. Alamanos and coworkers²⁵ also reported differences in age of peak incidence according to gender in a mainly white Greek population. The mean incidence rate was highest in the 45- to 64-year age group for women, whereas the incidence rate peaked in the age group 65 years and older for men.

Racial and ethnic factors

Multiple studies have indicated that individuals of African ancestry have a higher susceptibility to SSc and develop more severe disease. Laing and coworkers³⁰ examined racial differences among 514 female SSc patients, 23% of whom ($n = 117$) were African American. The annual incidence of SSc among African American women was 22.5 per million versus 12.8 per million among European American women ($P < .001$). In addition to having a higher incidence of SSc, African American women were more likely than European American women to develop diffuse disease (49.6% vs. 24.9%; $P < .001$). Pericarditis, pulmonary hypertension, pleural effusion, myositis, and an erythrocyte sedimentation rate of more than 40 mm/hr also were more frequent among African American women, whereas white women were more likely to have digital infarctions. Mayes and coworkers¹³ also reported

a higher prevalence of SSc in African Americans than in European Americans (prevalence ratio, 1.15; 95% CI, 1.02 to 1.30). This finding has been confirmed by Le Guern and coworkers,²⁴ who investigated the prevalence of SSc in a suburb of Paris, France. Among study participants, 26% were of non-European background with mainly northern and sub-Saharan African (16%), Asian, and Caribbean ancestry. The respective prevalence rates of SSc for Europeans and non-Europeans were 140.4 (95% CI, 112 to 170) and 210.8 (95% CI, 128 to 293), respectively, which results in a higher prevalence ratio of 1.5 among non-Europeans. As found in previous studies, non-Europeans were significantly more likely to have diffuse SSc (34% vs. 17%; $P = .04$) and interstitial lung disease (53% vs. 33%; $P = .06$).

Just as there are differences in disease type, there are dissimilarities in autoantibody profile among various ethnic groups. Mayes and coworkers¹³ reported that the anticentromere antibody was present in 27% of European American patients (97 of 359), whereas it was observed in only 9.7% of African American patients (13 of 134; $P < .001$). Reveille and coworkers³¹ reported similar results: anticentromere positivity was more common among European Americans (32% vs. 4%), whereas African American patients were more likely to test positive for anti-RNP antibody (5% vs. 29%) and anti-fibrillarin (4% vs. 17%). Steen and coworkers³² also reported that African American patients were more likely to have anti-topoisomerase I, anti-U1-RNP, and anti-U3-RNP (antifibrillarin) autoantibodies than were white patients and that pulmonary fibrosis was more frequent and more severe in this group with a corresponding decrease in survival. In a study of white Australians and nonwhite Thais with SSc, McNeilage and coworkers³³ reported a higher frequency of antitopoisomerase (76%) and a lower frequency of anticentromere antibody (2%) in the Thais compared with the Australians, of whom 26% had antitopoisomerase antibodies and 51% had anticentromere antibodies.

Gender differences

SSc occurs more frequently in women than in men, with most estimates of female-male ratios ranging from 4:1 to 6:1.³⁴ Reasons for this female preponderance are not clear. Hormonal and pregnancy-related events are obvious possibilities, but few published reports have investigated the association between previous hormone use or previous pregnancy and the subsequent development of SSc. Cockrill and coworkers³⁵ reported that parity conferred an increased risk of SSc among 172 women with SSc compared with their healthy sisters ($n = 256$) in the United States. However, Pisa and coworkers³⁶ reported a reduced risk of SSc among parous women compared with nulliparous women in Italy (odds ratio, 0.3; 95% CI, 0.3 to 0.7) in a study of 46 SSc cases versus 153 controls.

Microchimerism has been proposed as a risk factor for SSc. Iatrogenic microchimerism is a well-known consequence of allogeneic hematopoietic stem cell transplantation. However, natural microchimerism, caused by cell transfer between mother and fetus during pregnancy and resulting in the persistence of small populations of genetically distinct individuals, is a relatively newly recognized concept.³⁷ The persistence of these cells over decades has been proposed as a contributing factor in autoimmune disease pathogenesis.³⁸ However, the presence of these microchimeric cells in normal individuals as well as in SSc patients raises questions about the pathogenic role of this phenomenon.

An alternative explanation for female predominance involves X chromosome abnormalities, specifically the preferential skewing of X chromosome inactivation toward one parental source in the peripheral blood of SSc patients.³⁹ However, the pathogenetic mechanism in terms of increased susceptibility to autoimmunity in general and to SSc in particular has not been established.

Finally, Dieudé and coworkers⁴⁰ reported that a variant of the *IRAK1* (interleukin-1 receptor-associated kinase 1) gene on the X chromosome was found more frequently in SSc women than in controls. This suggests that either this gene variant or one nearby on the X chromosome may contribute to the female preponderance in SSc.

Familial systemic sclerosis and genetic influences

Familial aggregation is more common than expected for this relatively rare disease. Arnett and coworkers⁴¹ reported 11 cases of familial SSc involving first-degree relatives in a U.S. cohort of 703 cases, resulting in a prevalence of 1.6% for familial occurrence. This finding was similar to results of an earlier study by Englert and coworkers⁴² in which 10 familial cases involving first-degree relatives were reported among 710 SSc patients in Australia (prevalence, 1.6%). Assassi and coworkers⁴³ investigated the disease characteristics of 18 multiple-case families identified in a registry of 710 SSc families (prevalence, 2.5%). The observed SSc-related antibody concordance

within each multiple-case family was statistically greater than expected by chance alone ($P = .007$). Similarly, HLA haplotype sharing among the affected sibling pairs was more common than expected ($P = .011$). A family history of SSc, although infrequent, remains the strongest risk factor for SSc yet identified. The familial occurrence of a disease can be the result of shared genetic predisposition and/or exposure to common environmental factors in early life.

In addition to the occurrence of SSc in more than one family member, there is evidence that multiple autoimmune diseases cluster within families of patients with SSc. A study of 121 French families,⁴⁴ a study of 1071 U.S. cases,⁴⁵ and a U.S. population-based study⁴⁶ all came to the conclusion that autoimmune diseases occur more frequently in relatives of SSc cases than would be expected in the general population, although the specific diseases and methods of case ascertainment varied widely among these reports. However, the weight of evidence supports the notion that common genetic factors, shared among many autoimmune diseases, contribute to disease susceptibility.

Genetics of systemic sclerosis

Two large genomewide association studies^{47,48} have confirmed the findings of a previous large study⁴⁹ regarding the association of HLA with SSc susceptibility. In addition, over 30 non-major histocompatibility complex gene variants have been associated with increased susceptibility to SSc.⁵⁰ Most of these SSc susceptibility genes are similar to those identified for systemic lupus erythematosus, rheumatoid arthritis, and other autoimmune disorders and involve pathways in both the innate and the adaptive immune systems. However, with few exceptions, the precise identification of the causal variants and their role in contributing to autoimmunity have not been determined. The particular genetic associations are most striking when the disease is subdivided by autoantibody groups, which suggests that the genetic contribution to SSc pathogenesis differs in these subsets. Geographic differences in the distribution of HLA alleles, as well as non-HLA genetic variants, may contribute to the geographic variation in rates of disease occurrence noted earlier in the chapter.

Environmental considerations

Multiple environmental exposures, particularly exposure to organic solvents and silica dust, have been reported to be associated with the subsequent development of SSc. A meta-analysis of 11 studies (encompassing 1291 cases and 3435 controls) found that the reported risk of SSc was highly variable from study to study and that there appeared to be publication bias, which suggests that studies with positive results were more likely to be published than those with negative findings.⁵¹ Men were at higher risk than women, but the majority of patients did not report exposure to these substances. Thus the role of environmental triggers remains unclear. (For more detailed discussion, see Chapter 147.)

Survival

Improved survival rates for SSc have been reported in recent studies^{13,52} compared with previously published survival data.^{53,54} A survival study¹⁶ of 915 Italian SSc patients showed that patients recruited from 1986 to 1999 had a significantly higher 10-year survival rate than those enrolled from 1955 to 1985 (76.8% vs. 60.6%, respectively; $P < .001$). However, the 10-year survival rates in recent studies also vary, ranging from 55.1%¹³ to 76.8%.¹⁶ The observed improvement in survival might be secondary to earlier diagnosis in recent years (lead-time bias); however, recent improvements in treatment of life-threatening complications of SSc are also likely contributing factors. Steen and Medsger⁵⁵ detailed the changes in organ-specific causes of mortality over 25 years at a single university center. This study showed that diseases of the lung, including both pulmonary fibrosis and pulmonary hypertension, have become the primary cause of SSc-related deaths, replacing SSc renal crisis, which was formerly the leading cause of mortality before the widespread use of angiotensin-converting enzyme inhibitors.

LONG-TERM SURVIVAL OF PATIENTS WITH SYSTEMIC SCLEROSIS

Fig. 140.2 Proportion of surviving patients with systemic sclerosis according to the presence or absence of cardiac, renal, or pulmonary involvement. (Adapted from Ioannidis JP, Vlachoyiannopoulos PG, Haidich AB, et al. Mortality in systemic sclerosis: an international meta-analysis of individual patient data. *Am J Med* 2005;118:2-10.)

An international meta-analysis⁵⁶ of individual patient data regarding mortality in SSc has been reported encompassing 1645 incident cases (enrollment within 6 months of physician diagnosis). Data came from seven medical centers in the United States, Europe, and Japan, and standardized definitions for organ involvement were used. All cohorts showed significantly increased standardized mortality ratios in comparisons based on age- and sex-matched country-specific life tables. However, the mortality ratios varied widely, ranging from 1.5 to 7.2, depending on country and the referral base of the involved center. After adjustment for age, sex, and year of enrollment, the presence of anti-topoisomerase I antibodies, as well as the presence of renal, cardiac, and pulmonary involvement, independently increased the risk of death. Renal, cardiac, and pulmonary involvement tended to occur together ($P < .001$). Fig. 140.2 shows the long-term survival of these patients according to the presence or absence of cardiac, renal, or pulmonary involvement. This study confirms the finding of previous studies that the main predictor of mortality is the presence and severity of renal, cardiac, and pulmonary involvement. Laboratory findings such as elevated erythrocyte sedimentation rate, anemia, and proteinuria^{52,57} have also been linked to poor survival.

Not all studies, however, have reported an improvement in survival. For example, Elhai and coworkers⁵⁸ performed a meta-analysis of nine studies which suggested that the standardized mortality ratio for SSc has not changed significantly in the last 40 years.

Two studies^{59,60} investigated SSc mortality rates in the United States using data from the National Center for Health Statistics. In these two studies, the rates of death related to SSc were higher in the African American population than in the European American population. This finding might be related to the higher prevalence and more aggressive disease seen in the African American population and to the disparity in socioeconomic parameters. In another study of SSc patients, a higher inpatient mortality also was seen in African Americans and other nonwhites than in European Americans in South Carolina⁶⁰; this difference remained even after adjustment for other sociodemographic and clinical factors.

Assessing disease activity and outcome in systemic sclerosis (scleroderma)

■ DINESH KHANNA

- The modified Rodnan skin thickness score assesses 17 body areas and assigns a value of 0 to 3 based on palpation of the skin. Higher scores indicate worse disease and generally correlate with worse internal organ involvement and greater mortality.
- The European Scleroderma Study Group scale is an instrument that includes a 10-point index to measure disease activity (physical or laboratory findings that vary over time and are potentially modifiable by treatment).
- Disease severity, or the effect of disease on organ function, which is either reversible or irreversible, is best assessed with the Systemic Sclerosis Severity Scale.
- The Scleroderma Health Assessment Questionnaire Disability Index is a modified version of the Health Assessment Questionnaire that has been validated in patients with scleroderma and is used to assess functional ability.
- Multiple outcome measures (e.g., modified Rodnan skin score [skin], percent predicted forced vital capacity [lung]) have been found to be feasible, reliable, and valid for clinical trials in scleroderma.
- Effort is undergoing to develop a composite index for clinical trials in patients with scleroderma.

INTRODUCTION

Substantial progress has been made in the development and validation of outcome measures for systemic sclerosis (scleroderma [SSc]).^{1,2} The discussion here is focused on disease activity and disease severity measures in SSc, and an update is provided on outcome measures currently used in clinical trials and clinical care. This chapter does not address outcome measures developed and validated for localized scleroderma or juvenile scleroderma.

MEASUREMENT PROPERTIES OF AN INSTRUMENT: FEASIBILITY, RELIABILITY, AND VALIDITY

An outcome measure should be feasible, reliable, and valid. A feasible measure is accessible, easily interpretable, and associated with low cost. Reliability (precision) is the extent to which a measure yields the same score each time that it is administered if the underlying health condition has not changed. A reliability coefficient of .90 (meaning that 90% of the score is accurate whereas the remaining 10% denotes error) is considered satisfactory for individual comparisons, and .70 or higher is deemed satisfactory for group comparisons.³ Validity is the extent to which the score that a health measure yields accurately reflects the health concept and includes face (sensible), content (comprehensive), construct (measures or correlates with a theorized health construct), and criterion validity (predicts or correlates with the “gold standard”). Sensitivity to change, an aspect of construct validity, assesses whether an instrument score changes in the right direction when the underlying health construct changes; the ability of an instrument to detect clinically important change is crucial to its usefulness as an outcome measure in a clinical trial.

MEASURING DISEASE ACTIVITY AND SEVERITY IN SCLERODERMA

Investigators agree that assessment of disease activity and severity is an important goal in SSc. Based on previous consensus reached in other rheumatic diseases,⁴ activity is defined as the aspect of disease that varies over time and has the potential to be reversible spontaneously or with therapy (e.g., tendon friction rubs, acute-phase reactants, inflammatory polyarthritis). Damage is the cumulative burden of a disease at a given time and is generally irreversible (e.g., calcinosis, end-stage pulmonary fibrosis). Both activity and damage contribute to disease severity; early in SSc, activity predominates, whereas later in the disease, damage is more likely to be the dominant element.⁵

Disease activity in scleroderma

The European Scleroderma Study Group has proposed a composite index to assess SSc-related disease activity in routine clinical care.^{6,7} The index is feasible because it includes measures (clinical examination, patient assessment of activity over the last month, laboratory measures, and percent predicted diffusing capacity of the lung for carbon dioxide [%DLCO]) collected in routine practice. It has face and content validity, and it is scored on a 0 (no activity) to 10 (severe activity) basis, with the greatest weight assigned to deterioration of the relevant organ system as evaluated by the patient with respect to the previous month. The tests required to calculate the index are inexpensive and easily carried out in routine clinical care. The index does have a few limitations: (1) it was developed in patients with established disease and has not yet been studied in those with early SSc, in whom the disease is likely to be active; (2) three patient-reported items relate to changes in skin, vascular, and cardiopulmonary symptoms in the past month, and such changes in activity indices may be challenging because they fail to capture *persistent* activity and might be difficult to determine every month⁸; and (3) the index has not been developed for clinical trials, and its sensitivity of change has not been published.

Assessment of disease severity

A measure of disease severity encompasses both disease activity and damage and should be associated with or predict SSc-associated morbidity and mortality.⁵ The revised Medsger severity index⁸ was developed by international scleroderma experts using consensus methodology, followed by prospective data collection. The authors identified nine organ systems and variables for each organ system that can be used to define severity. The nine organ systems are general, peripheral vascular, skin, joint/tendon, muscles, gastrointestinal tract (GIT), lung, heart, and kidney. Each system is scored from 0 (uninvolved) to 4 (end-stage disease). The individual organ system severity scores have been shown to predict survival in a large observational cohort.⁹ The severity index is not weighted and should therefore not be summed to obtain a “global” severity scale score.

OUTCOME MEASURES IN SCLERODERMA

Although many novel outcome measures are currently in development, this section discusses outcome measures (Table 141.1) that have been shown to be feasible, reliable, and valid in clinical trials and clinical care.

TABLE 141.1
Feasible, reliable, and valid measures used in clinical trials and clinical practice

Instruments	Ready for RCT	Used in clinical practice
Health-related quality of life		
SF-36 version 2*	Yes	No
Health Assessment Questionnaire–Disability Index*	Yes	Yes
SF-6D*	Yes	No
Patient Reported Outcomes Measurement Information System (PROMIS)*	Yes	Yes
UK Functional Scale*	Yes	Yes
Skin		
Modified Rodnan skin score	Yes [†]	Yes
Durometer	Yes [†]	No
Musculoskeletal		
Tendon friction rubs assessed by the investigator	Yes [†]	Yes
Tender joint count	Yes [†]	Yes
Serum creatine phosphokinase value	Yes	Yes
Cochin Hand Function Scale*	Yes	Yes
Hand Mobility in Scleroderma scale	Yes	No
Mouth Handicap in Systemic Sclerosis scale*	Yes	Yes
Cardiac		
Echocardiogram with Doppler imaging	Yes [†]	Yes [§]
Right-sided heart catheterization	Yes	Yes [§]
6-Minute walk test	Yes	Yes
Borg dyspnea index (administered immediately after the 6-minute walk test)	Yes	Yes
Pulmonary		
Pulmonary function test with diffusion capacity	Yes	Yes
High-resolution computed tomography	Yes [†]	Yes [§]
Validated measure of dyspnea*	Yes	No
Breathing VAS from the SSc HAQ*	Yes	Yes
Gastrointestinal		
Gastrointestinal VAS from the SSc HAQ*	Yes	Yes
UCLA Scleroderma Clinical Trial Consortium Gastrointestinal Tract 2.0*	Yes	Yes
Body mass index	Yes	Yes
Renal		
Estimated creatinine clearance	Yes	Yes
Systolic and diastolic blood pressure	Yes	Yes
Serum creatinine	Yes	Yes
Raynaud phenomenon		
Raynaud's Condition Score*	Yes	No
Number of attacks as reported by the patient*	Yes	Yes
Duration of attacks*	Yes	Yes
Raynaud VAS from the SSc HAQ*	Yes	Yes
Patient assessment of the overall Raynaud phenomenon on a VAS*	Yes	Yes
Patient assessment of pain, numbness, and tingling on a VAS*	Yes	Yes
Physician assessment of the overall Raynaud phenomenon on a VAS	Yes [†]	Yes
Digital ulcer		
Active digital tip ulcer count on the volar surface	Yes [†]	Yes
Digital ulcer VAS from the SSc HAQ*	Yes	Yes
Biomarkers		
Acute-phase reactants	Yes	Yes
Serum BNP/NT-Pro BNP	Yes	Yes

*Completed by the patient.

[†]Assessed by the same investigator.

[‡]Standardized central reading mechanism strongly encouraged in multicenter RCTs.

[§]Feasibility may be limited because of cost or lack of availability in clinical care.

^{||}Quality control strongly encouraged in multicenter RCTs.

^{||}For patients with pulmonary arterial hypertension.

HAQ, Health Assessment Questionnaire; NT-Pro BNP, N-terminal brain natriuretic peptide; RCT, randomized controlled trial; SF-36, Medical Outcomes Study Short-Form 36-Item Health Survey; SSc, systemic sclerosis; VAS, visual analogue scale.

Modified from Khanna D, Lovell D, Giannini E, et al. Development of a provisional core set of response measures for clinical trials of systemic sclerosis. *Ann Rheum Dis* 2008;67:703-9.

Measuring skin disease in scleroderma

SSc is subclassified into “diffuse cutaneous” or “limited cutaneous” SSc based on the extent of skin involvement.¹⁰

The *modified Rodnan skin score* (MRSS), a measure of skin thickness,^{11,12} has been used as the primary outcome measure in clinical trials of diffuse cutaneous SSc (dcSSc) (see Fig. 142.9). Measurement of skin thickness is used as surrogate measure of disease severity and mortality in patients with dcSSc—an increase in skin thickening is associated with involvement of internal organs and increased mortality.¹² It is generally accepted that the MRSS tends to worsen in early disease and improve in late disease, although the time of peak involvement remains poorly defined. “Early” dcSSc is often defined as the period of rapidly and severely increasing induration (“thickening”) of the skin, which has been thought to peak 1 to 3 years after onset of the disease.¹³ The MRSS was found to be feasible, reliable, valid, and sensitive to change in multicenter clinical trials.¹¹ For example, the MRSS was able to differentiate between treatment with methotrexate and placebo in early diffuse SSc¹⁴ and between cyclophosphamide and placebo in the diffuse SSc subset in the Scleroderma Lung Study.¹⁵ The MRSS also improved in the Autologous Stem Cell Transplant Study. However, recent analysis from three large randomized controlled trials (RCTs) of dcSSc showed that the mean MRSS improved regardless of disease duration at baseline—a general tendency for skin to soften over time was noted, and no difference in this tendency was found in patients with different disease durations at baseline.¹⁶ In another analysis of 629 patients who participated in dcSSc trials, the average MRSS improved in the trials; in patients with disease of less than 18 months’ duration, the MRSS improved in 63% and worsened in 37%. In patients with a disease duration of 18 months or longer, the MRSS improved in 81% and worsened in 19%.¹⁷ This observation differs from the natural history of skin thickening previously reported and has important implications in “prevention of worsening” study designs when using skin softening as an endpoint.¹⁸ Approval agencies continue to consider the MRSS an acceptable primary outcome. If incorporated, the RCT should last at least 52 weeks and the study should also incorporate measures to show improvement in patient-reported outcomes and stabilization of lung and other internal organ involvement (discussed later).

Durometers are hand-held devices used to measure the hardness of material in internationally standardized durometer units. The durometer was included in a multicenter study of early dcSSc and was found to be feasible, reliable, valid, and sensitive to change.¹⁹ High correlation was found between the MRSS and durometer units at baseline (coefficient ≥ 0.69) and during follow-up in the changed (coefficient ≥ 0.70) scores.¹⁹ Use of the durometer may be limited because of its cost.

Other methods have been proposed for measurement of skin disease in SSc, including skin ultrasonography, elastometry, magnetic resonance imaging, and other radiographic techniques,²⁰ but they lack data on sensitivity to change and have not been applied in a multicenter setting.

Measuring musculoskeletal involvement in scleroderma

Musculoskeletal involvement occurs in 40% to 80% of patients and is most problematic in early dcSSc.²¹ Tendon friction rubs (TFRs) are grating, “squeaking” sensations detected on passive or active motion of the affected tendon in patients with SSc. On physical examination, TFRs are most commonly present in the flexor and extensor tendons of the fingers and wrists and the anterior tibial and peroneal tendons. TFRs are associated with a higher likelihood of the development of dcSSc and more severe disease—a higher MRSS, joint contractures, greater physical disability, higher prevalence of cardiac or renal involvement, and decreased survival.^{22,23} TFRs should be measured by the same assessor in an RCT and be incorporated as a secondary outcome measure. In clinical care, the presence of a TFR requires careful monitoring for the development of dcSSc and a more severe disease course.

Hand disability in SSc can be evaluated by using the Cochin Hand Function Scale (CHFS), an 18-item instrument that relates to hand functionality or disability during various tasks in different settings (e.g., in the kitchen, dressing oneself, hygienic tasks, in the office).²⁴ It has three scales—dexterity, rotational movement, and flexibility of the first three fingers. The instrument is feasible and has shown acceptable reliability in patients with SSc.²⁵ The CHFS was found to be sensitive to change in an intervention study that incorporated hand massage of connective tissue and home exercises.²⁶ It is an acceptable secondary outcome measure to assess improvement in hand function.

The Hand Mobility in Scleroderma (HAMIS) is a nine-item performance-based test designed to examine the effects of SSc on hand mobility and

function and is preferably administered by an occupational therapist or research physician.^{27,28} The HAMIS test consists of nine items that assess finger flexion and extension, abduction of the thumb, pincer grip, finger abduction/swelling, dorsal extension and volar flexion of the wrist, and pronation and supination. The HAMIS instrument has shown acceptable reliability and validity. It was found to be sensitive to change in an intervention study that incorporated hand massage of connective tissue and home exercises,²⁶ and it complements the CHFS in studies focused on the hands.

The Mouth Handicap in Systemic Sclerosis scale was developed to assess attributes of mouth involvement in SSc.²⁹ It is a 12-item scale with acceptable reliability and validity. It has three scales that represent handicap associated with a reduction in mouth opening, handicap associated with sicca syndrome, and aesthetic concerns. Its sensitivity to change was shown in an intervention program that included massage of the connective tissue of the face.³⁰

There is great interest in assessing radiographs and ultrasound images in patients with SSc, and erosive disease is seen in 5% to 40% of patients on plain radiographs.³¹ This proportion is higher with new imaging modalities.

Measuring lung disease in scleroderma

Pulmonary disease is now the leading cause of death in patients with SSc.³² Pulmonary disease in SSc falls into two major categories: interstitial lung disease (ILD) and pulmonary arterial hypertension (PAH). Several recent clinical trials have specifically focused on lung disease in SSc.^{15,33,34}

Pulmonary function tests (PFTs) in patients with SSc-ILD demonstrate a restrictive lung defect with decreased percent predicted forced vital capacity (%FVC) and percent predicted diffusing capacity for carbon monoxide (%DLCO). PFTs are feasible in large RCTs of SSc-ILD.^{15,33,34} %FVC has been used as the main parameter of restrictive lung disease and %DLCO for pulmonary vascular disease. %FVC was able to differentiate between the active group (cyclophosphamide [CYC]) and the placebo group in the Scleroderma Lung Study-1 (SLS). Low %FVC predicts morbidity and mortality associated with SSc-ILD³³ and is sensitive to change in multicenter RCTs.^{15,33} Serial measurements of lung function with PFTs are also prognostic, and a 15% decline in %DLCO at 3-year follow-up corresponds to a significantly increased risk for mortality in patients with idiopathic pulmonary fibrosis,^{35,36} although this has not been assessed for SSc-ILD. %DLCO is sensitive but not specific for SSc-ILD or SSc-PAH and can decline in both diseases. It did not differentiate between the active and placebo groups in two SSc-ILD studies.^{37,38} A disproportionate decline in %DLCO may indicate PAH.

Quality control programs are key for RCTs in SSc-ILD and were recently discussed in detail.^{38,39} Such programs were implemented in the SLS-1 with satisfactory results with respect to achievement of acceptable test quality and are feasible in RCTs.

High-resolution computed tomography (HRCT) of the lungs has been incorporated successfully in recent RCTs.^{15,34} HRCT has two key roles in clinical trials of SSc, as recently discussed³⁸: (1) detection and staging of baseline severity, which can be used effectively for cohort enrichment, and adjusting for baseline severity in key treatment effect analyses (because it is likely that a treatment effect may differ in those with mild and in those with extensive lung disease) and (2) as a surrogate endpoint or more accurate measure of serial change. HRCT can be used to diagnose and quantify the degree of fibrosis, thus supporting its face and content validity. The feasibility of HRCT in multicenter RCTs was demonstrated in two recent studies involving SSc-ILD.^{15,34} The reliability of HRCT was demonstrated in the SLS trial,¹⁵ in which good interreader agreement was found for determination of the absence or presence of pure ground-glass opacity ($\kappa = .76$) and fibrosis ($\kappa = .74$) but fair agreement for honeycombing ($\kappa = .29$). In the SLS a higher degree of the extent of fibrosis seen on baseline HRCT was predictive of the rate of decline in FVC in subjects receiving placebo,³⁹ as well as the response to CYC therapy; patients with the most extensive fibrosis on baseline HRCT responded the greatest to CYC treatment.⁴⁰ A greater extent of pulmonary fibrosis on HRCT correlated well with lower FVC and DLCO values on PFTs. In a recent analysis of 215 patients with SSc monitored for 10 years,⁴¹ an increased extent of overall disease (as defined by the degree and coarseness of reticulation [fibrosis] and the proportion of ground-glass opacity) greater than 20% on HRCT correlated with an increase in mortality (hazard ratio, 2.48; $P < .0005$). Therefore, HRCT can be used for the diagnosis of ILD, cohort enrichment for RCTs, and therapeutic decision-making regarding the use of immunosuppressive agents in clinical care.

The 6-minute walk test—an outcome measure for pulmonary arterial hypertension

The 6-minute walk test (6MWT) measures the distance that a person can walk in 6 minutes and has been used extensively as an outcome measure in

patients with various cardiac and pulmonary diseases. The 6MWT is currently the most widely used primary endpoint for studies investigating PAH, including SSc-related PAH. It has been successfully incorporated into trials of SSc-related PAH and was able to differentiate between active and placebo treatment in a trial of epoprostenol for SSc-related PAH.⁴² Pain and musculoskeletal involvement can influence the 6MWT, and it is not always solely reflective of changes in cardiopulmonary involvement when used in patients with SSc.^{43,44} The 6MWT is not sensitive to change in SSc-ILD. It should not be used as a screening measure but may provide prognostic information in patients with SSc-PAH.

Dyspnea indices

Patient-reported outcome measures are important for assessing the efficacy of a treatment. The *Mahler dyspnea index*⁴⁵ was used in the SLS and assesses the level of dyspnea. Baseline scores depend on ratings in three different categories: functional impairment, magnitude of the task, and magnitude of effort. Baseline scores were able to discriminate between moderate and severe physiologic parameters of breathing (%FVC and %DLCO) and correlated well with the baseline breathing visual analogue scale (VAS; $r = .61$).⁴⁶ The Mahler transitional dyspnea score was able to differentiate between patients receiving CYC and placebo in the SLS at 1 year, thus demonstrating its sensitivity to change.⁴⁷ Another instrument used is the Saint George Respiratory Questionnaire, but it lacks data regarding sensitivity to change.

The *breathing VAS scale* in the *Scleroderma Health Assessment Questionnaire* (S-HAQ) allows patients to assess their degree of difficulty in performing daily activities because of shortness of breath on a continuous 100-mm scale.⁴⁸ The VAS discriminates between moderate and severe reductions in lung function, correlates well with the Mahler dyspnea index ($r = .61$), and was shown to be sensitive to change in an SSc cohort⁴⁸; it did not differentiate between CYC and placebo in the SLS-I.

Other outcome measures for cardiopulmonary disease in patients with SSc have been proposed, including exercise echocardiography and magnetic resonance imaging, but await full validation.

Measuring gastrointestinal tract disease in scleroderma

GIT disease occurs in approximately 90% of patients with SSc. Although radiologic tests are the cornerstone for the diagnosis of specific GIT involvement, their feasibility is questionable in multicenter trials, and radiologic tests may be positive in a significant proportion of patients without symptoms.⁴⁹ Furthermore, many patients with SSc have multiple types of GIT disease with overlapping symptoms, thus making quantification of GIT disease in patients with SSc extremely challenging. A recent Delphi panel⁵⁰ and separate expert consensus⁵¹ recommended the use of patient-reported outcome measures and the body mass index as core set measures. Aside from a simple GIT VAS (part of the S-HAQ⁴⁸) that assesses interference in daily activities, a comprehensive scleroderma gastrointestinal instrument has recently been developed under Food and Drug Administration guidelines. The University of California Scleroderma Clinical Trial Consortium Gastrointestinal Instrument (UCLA SCTC GIT 2.0) is a validated, patient-reported outcome measure to assess GIT symptoms and health-related quality of life (HRQOL) in patients with SSc.⁵²⁻⁵⁴ This 34-item instrument has seven scales—reflux, distention/bloating, diarrhea, fecal soilage, constipation, emotional well-being, and social functioning—and a total GIT score. The instrument is feasible and has been shown to have acceptable reliability (test-retest and internal consistency) and validity.⁵³ All scales are scored from 0 (better HRQOL) to 3 (worse HRQOL), except for the diarrhea and constipation scales, which range from 0 to 2 and 0 to 2.5, respectively. Participants who rated their GIT disease as mild had lower scores on all seven scales. Symptom scales were also able to discriminate subjects with corresponding clinical GIT diagnoses. The total GIT score is the average of six of seven scales (excludes constipation) and ranges from 0 (better HRQOL) to 2.83 (worse HRQOL). The instrument is sensitive to change in patient self-rated severity, and minimally important differences have been published.⁵⁵ In addition, the instrument has been recently translated into multiple languages and is available free online at <http://uclascleroderma.researchcore.org/>.

Other outcome measures for GIT disease in patients with SSc have been proposed or are under development, including bioelectric impedance analysis, manometry, gastric transit time, endoscopy, and measures of malabsorption.²⁰ There is lack of data on the sensitivity of these measures to change in SSc.

Measuring vascular disease in scleroderma: Raynaud phenomenon and digital ulcers

The Raynaud phenomenon (RP) occurs in approximately 90% of patients with SSc. Similarly, digital ulcers (DUs) are common in those with SSc and result in digital ischemia and gangrenous lesions, as well as skin breakdown. Several clinical trials have examined the efficacy of various interventions for RP and DUs in patients with SSc.⁵⁶⁻⁵⁸ The Raynaud's Condition Score⁵⁶ (RCS) is now the standard outcome for use in clinical trials of RP and is calculated by summing the daily score over a period of 1 or 2 week.⁵⁶ The RCS assesses the level of difficulty experienced because of RP each day (anchored from "no difficulty" to "extreme difficulty") on a 0- to 100-mm VAS or an 11-point Likert scale. Other measures ready for RCTs include the duration of RP attacks, frequency of RP attacks, and patient and physician global assessment.⁵⁶ However, clinical trials in patients with RP are associated with marked variability in individual outcome measures, and a composite measure is needed.⁵⁹ The S-HAQ VAS for RP (assesses interference in daily activities as a result of RP) is also feasible, reliable, and valid.⁵⁶

Other laboratory measures include the cold stimulus fingertip lactecmy test, laser Doppler flowmetry, and others. These measures are useful for proof-of-concept studies but lack feasibility in large multicenter trials.

Measuring ischemic digital ulcers in scleroderma

Methods considered for measuring DUs include standardized photographs, measurement of the size of ulcers, patient and physician global assessment, simple counts of ulcer frequency, and time for ulcers to heal. A definition of DU has recently been developed with consensus methodology,⁶⁰ and it is defined as loss of surface epithelialization at or distal to the proximal interphalangeal joint and does not include fissures or cracks in the skin or areas of calcium extrusion from calcinosis cutis. In a recent study aimed at assessing the reliability of defining DU, a high level of intrarater reliability ($\kappa = .81$) but poor interrater reliability ($\kappa = .46$) was noted, thus suggesting that the same observer should assess DUs in RCTs.⁶¹ The DU count was found to be feasible, reliable, valid, and sensitive to change in large RCTs involving DUs.^{60,62} The S-HAQ VAS for DU (assesses interference in daily activities because of DUs) was shown to be feasible, reliable, valid, and sensitive to change in a large SSc cohort.⁴⁸

Measuring physical function and health-related quality of life

SSc is associated with detrimental effects on physical functioning and emotional and psychological well-being, and different measures have been used.

The Short Form 36 and Health Assessment Questionnaire–Disability Index

Both the Medical Outcomes Study Short-Form 36-Item Health Survey (SF-36) and the Health Assessment Questionnaire–Disability Index (HAQ-DI) have been extensively incorporated into multicenter clinical trials of SSc.^{46,63,64} Both instruments have face and content validity because they measure constructs that are important to patients with SSc, and both measures are easy to administer. Although test-retest reliability for the SF-36 and HAQ-DI has been acceptable in patients with other rheumatologic diseases, no study has formally evaluated reliability in those with SSc. The SF-36 and HAQ-DI were found to be responsive to change in two RCTs.^{63,64} In addition, baseline HAQ-DI scores predict mortality in patients with early dcSSc.^{48,65} The SF-36 and HAQ-DI complement each other, and both should be incorporated in clinical trials as measures of HRQOL.

The *UK Functional Score* (UKFS) is a self-reported, 11-item functional questionnaire. It includes nine items related to upper extremity function and two items related to muscle weakness and lower extremity function.⁶⁶ The UKFS is able to differentiate between limited SSc and dcSSc ($P < .05$) and is highly correlated with the HAQ-DI (coefficient of .90). It was found to change during a longitudinal study, with a correlation of .59 with the HAQ-DI.^{67,68}

Patient-Reported Outcomes Measurement Information System

The National Institutes of Health Patient-Reported Outcomes Measurement Information System (PROMIS) Roadmap initiative (www.nihpromis.org) is a cooperative research program designed to develop, evaluate, and standardize item banks for measuring patient-reported outcomes across different medical conditions, as well as the U.S. population.⁶⁹ The PROMIS has validated instruments for assessing physical, mental, and social health in adults

and pediatric populations. The instrument can be given as a short form (paper and pencil) or via computer (computerized adaptive tests).^{70,71}

Preference-based measures for health-related quality of life: the Short Form 6D

The Short Form 6D (SF-6D) is a preference-based measure that was derived from the SF-36 by using population-based utilities of health states. Preference-based measures are used in decision and cost-effectiveness analyses. The SF-6D is feasible because it only requires completion of the SF-36. Its test-retest reliability was found to be acceptable. Construct validity was confirmed by showing good correlation with the HAQ-DI and with patient global assessment in a recent clinical trial.⁷² The SF-6D was able to discriminate among the baseline severity of the HAQ-DI and patient global assessment and was sensitive to change.

Other generic and disease-specific measures have been tested in patients with SSc, including the Scleroderma Assessment Questionnaire and measures of anxiety, fatigue, and depression.⁷³ These instruments have not yet been shown to be sensitive to change in SSc.

Biomarkers for scleroderma

Vascular (von Willebrand factor [vWF]), T-cell (soluble IL-2 receptor [sIL-2R]), B-cell (autoantibodies), and fibroblast (type III procollagen N-terminal peptide propeptide [PIIINP]) candidate markers have been proposed as biomarkers for SSc. sIL-2R, vWF, and PIIINP were recently assessed in an open-label trial of infliximab and SSc.⁷⁴ Serum markers were demonstrated to be feasible, and PIIINP and vWF showed change over a 6-month period. Other novel markers include myofibroblast staining, four-gene marker (transforming growth factor- β -regulated and interferon-regulated genes),

and gene expression profiling. Recent data suggests their utility in clinical care and predicting responders to immunosuppressive therapies.^{74a} These biomarkers should be included as exploratory endpoints in ongoing large clinical trials to assess their utility as outcome measures. Other readily available markers are acute-phase reactants (erythrocyte sedimentation rate, C-reactive protein) that are associated with disease activity⁶ and predict mortality,^{48,75} and they were proposed as validated biomarkers by scleroderma experts.⁷⁶ Serum creatine phosphokinase is a widely used marker of muscle activity and damage, and N-terminal brain natriuretic peptide has recently been shown to predict incident cases of PAH.^{77,78} Scleroderma-specific autoantibodies are valuable for predicting skin, vascular, and internal organ involvement. Autoantibodies are useful for cohort enrichment,⁷⁹ but their role as an outcome measure in the context of clinical trials still needs to be demonstrated.

CONCLUSION

In the past decade an increase in the development and validation of several outcome measures in patients with SSc has taken place, and these measures have been implemented in several clinical trials. Effort is under way to develop a composite index for scleroderma.^{50,80}

Clinical features of systemic sclerosis

■ MARCY B. BOLSTER ■ RICHARD M. SILVER

- Systemic sclerosis (SSc) is an autoimmune disease characterized by microvascular damage and excessive connective tissue deposition in skin and internal organs.
- Lung disease is the leading cause of mortality, and efforts at early detection of pulmonary arterial hypertension (PAH) and interstitial lung disease (ILD) are warranted.
- Cardiac involvement is a poor prognostic indicator. Cardiac magnetic resonance imaging is a useful tool for evaluating myocardial function and perfusion.
- Autoantibodies help characterize disease subsets and risks of visceral involvement, and include anticentromere antibody (limited cutaneous SSc and risk of PAH), antitopoisomerase antibody (diffuse cutaneous SSc and risk of ILD), and anti-RNA polymerase III antibody (diffuse cutaneous SSc and risk of renal crisis).
- There are new classification criteria inclusive of many clinical features of systemic sclerosis that enables classification of patients with definite SSc who previously fell outside of the ACR criteria for the disease.
- Gastrointestinal involvement can affect any or all of the alimentary tract and is a prominent symptom in nearly all patients with SSc.
- Depression, often overlooked, is pervasive in patients with SSc.

HISTORICAL BACKGROUND

The first convincing description of scleroderma was by Carlo Curzio in 1753, and the term *sclerodermie* first appeared in the mid-19th century.¹ In 1862 Maurice Raynaud described tricolor vasospastic changes.² Osler referred to the systemic nature of the disease in the 1894 edition of his textbook of medicine (patients were “apt to succumb to pulmonary complaints or to nephritis”)³; and Klemperer and Boehr proposed in 1942 that scleroderma be considered a “systemic disease of the connective tissue.”⁴ A disorder first described in 1910 and originally termed *Thibierge-Weissenbach syndrome*⁵ was described in 1964 by Winterbauer as CRST syndrome (now known as *CREST syndrome* [calcinosis, Raynaud phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia]).⁶ LeRoy first elucidated the vascular hypothesis of the pathogenesis of systemic sclerosis (SSc) in 1975.⁷ Later, an autoimmune basis was established. More recently there has been remarkable progress in understanding the molecular mechanisms of fibrosis, microvascular injury, and the autoimmune process in this disease.

EARLY SYMPTOMS

Raynaud phenomenon is typically the earliest symptom in patients with SSc. Other frequent early symptoms are malaise, fatigue, arthralgia, and myalgia. Those patients who progress to develop diffuse skin involvement may initially have puffy fingers (Fig. 142.1) and carpal tunnel syndrome. Skin pigment changes may occur before or after the onset of the skin tightening. Occasionally a patient may describe the onset of gastroesophageal reflux symptoms or dyspnea predating the development of skin changes (e.g., systemic sclerosis sine scleroderma).

VASCULAR SYSTEM

Raynaud phenomenon is present in more than 95% of patients with SSc; its absence actually portends a worse prognosis. Raynaud phenomenon is defined as cold-induced vasospasm of the digits (fingers more than toes), rarely occurring in the ears, nose, or tongue. Although classically described as triphasic color changes of the digits, often a patient will not report all three hues. Initially pallor, a well-demarcated white color change, occurs in response to the vasospasm induced by cold exposure (Fig. 142.2). This may be followed by a dusky discoloration due to ischemia and desaturation of hemoglobin; subsequently, reactive hyperemia occurs and the digits turn red. In addition to the color changes, patients often experience numbness, tingling, and discomfort. A color chart of digital changes has been developed and validated to assist in identifying patients with Raynaud phenomenon, (Fig. 142.3) and, when used in conjunction with a short questionnaire, has 100% sensitivity and specificity for diagnosis of Raynaud phenomenon.⁸

In patients with limited cutaneous SSc (lcSSc), Raynaud phenomenon typically begins many years before the onset of skin or visceral disease. In patients with diffuse cutaneous disease (dcSSc), the onset of Raynaud phenomenon usually occurs simultaneously with or shortly after the onset of skin changes; however, in up to 20% of such patients skin thickening may precede the development of Raynaud phenomenon, and it is this reverse order of disease manifestations that seems to be associated with the development of diffuse skin involvement and also of scleroderma renal disease.⁹

Complications of Raynaud phenomenon include digital pitted scars (Fig. 142.4), fixed ischemic changes with threatened tissue loss, poorly healing digital ulcers, dry gangrene (Fig. 142.5), and autoamputation. Digital pits, one of the current SSc diagnostic criteria, represent areas of ischemic insult to the distal fingertip. Digital ulcers may occur at sites of trauma or may manifest solely as a result of vascular insufficiency. Digital ulcers may occur as necrotic debris with a “heaped up” appearance beneath the fingernail. Any of these digital ischemic manifestations may become secondarily infected. Vascular insult due to Raynaud phenomenon in patients with SSc is made more severe by the superimposed structural abnormality of the vascular disease that occurs due to intimal hyperplasia, medial hypertrophy, and adventitial fibrosis of the vessels (Fig. 142.6). These pathologic changes are not related to vasculitis but rather to a bland vasculopathy.

Digital ulcers may be exacerbated by macrovascular disease, typically ulnar artery vasoocclusive disease.¹⁰ Severe vasoocclusive disease occurs more frequently in patients with an anticentromere antibody.¹¹

SSc patients have characteristic microvascular changes that may be observed using widefield microscopy.^{12,13} Patients with lcSSc typically demonstrate nailfold abnormalities of capillary dilatation, termed the *slow phase*. In contrast, the *active phase*, characteristic of patients with dcSSc, is characterized by capillary dilatation and avascularity, or “drop-out” (Fig. 142.7). Nailfold capillaroscopy can assist in diagnosis and determination of prognosis in patients with new-onset Raynaud phenomenon. Characteristic nailfold capillary changes are under consideration to become part of new classification criteria for SSc in the interest of broadening the SSc inclusion criteria so that patients with earlier findings suggestive of SSc or patients with SSc sine scleroderma will be covered. One such proposal by Maricq and Valter includes the use of nailfold capillaroscopy, anticentromere anti-nuclear antibody assay, and telangiectasia as well as the extent of skin involvement to classify SSc into one of six classes.¹⁴ Additionally, a prognostic model using nailfold capillaroscopy has been evaluated to predict which patients with primary Raynaud phenomenon may be at risk of development of scleroderma spectrum diseases within 5 years. Nailfold capillary changes were been found to have 100% sensitivity in a group of 326 patients with

SSc.¹⁵ This validated model finds that capillary number and the presence of giant capillary loops or microhemorrhages are associated with the likelihood of developing scleroderma spectrum disease.¹⁶ Video capillaroscopy, a new tool permitting evaluation of the same capillaries on subsequent examinations, allows longitudinal follow-up of nailfold capillary changes with access to previous measurements.¹⁷

Fig. 142.1 The hand of a patient with early scleroderma demonstrating the "puffy" phase.

CUTANEOUS FEATURES

Three stages of skin changes may occur in patients with SSc. The initial stage, an inflammatory, edematous stage, is associated with puffiness of the hands and fingers (see Fig. 142.1). Pruritus may accompany this phase. Complications such as paronychia and sores over taut metacarpophalangeal (MCP), proximal interphalangeal (PIP), and distal interphalangeal (DIP) joints may develop with slow or poor healing. During this initial inflammatory phase, which may last for months, induration and thickening of the skin begin to develop.

Once the inflammatory phase quiets, a longer phase of progressive skin fibrosis may ensue, beginning with acral involvement, distal to the MCP joints, which may progress proximally. In patients who are developing diffuse skin changes there may be involvement of the skin on the face, hands, forearms, arms, chest, abdomen, thighs, legs, and feet. Patients with lcSSc have skin changes limited to the face, neck, and distal extremities. A small subset of patients with dcSSc may demonstrate truncal skin involvement without acral changes. The skin on the chest and abdomen may also be thickened in a bandlike distribution along pressure areas, such as the bra

Fig. 142.2 The hands of a patient with scleroderma who has active Raynaud phenomenon. There is well-demarcated pallor of the fingertips.

Fig. 142.3 A color chart card demonstrating the possibilities for color changes that a patient may identify as the cold-induced color changes of Raynaud phenomenon. (a, b, and f) Color changes seen in Raynaud phenomenon. (From Maricq HR, Weinrich MC. Diagnosis of Raynaud's phenomenon assisted by color charts. *J Rheumatol* 1988;15:454-59.)

line and belt region. Facial skin thickening does not distinguish between patients with limited and diffuse cutaneous disease, because it is typically involved in both subsets. Characteristic skin changes occur in the perioral region and include tightening and a tethering, causing a reduced oral aperture and “mauskopf” facies (Fig. 142.8). The front teeth may also appear to be prominent because of lip and gum retraction; gum retraction occurs due to both fibrosis and atrophy of the mandible.

Fig. 142.4 Digital pits on the fingertip of a patient with scleroderma.

Fig. 142.5 Digital gangrene on the fingertips of a patient with scleroderma.

Early in the disease course a patient may appear to have limited cutaneous disease, that is, distal skin thickening only; however, over the course of 2 years skin involvement may progress to include the proximal extremities and trunk (diffuse cutaneous disease). Therefore, it may be unreliable to classify a patient as having limited skin disease within the first 2 years from onset of skin changes.

Pigmentation changes occur during both the inflammatory-edematous and progressive fibrosis stages. Depending on the patient's natural skin tones, the skin may become hypopigmented or hyperpigmented. Some patients develop areas of depigmentation, particularly of the scalp, chest, and upper back and over areas of pressure such as the dorsum of the hand or pretibial regions. These areas of vitiligo give the skin a “salt and pepper” appearance owing to perifollicular sparing of pigment loss.

In patients with dcSSc, progressive fibrosis may be followed by a final stage of skin softening, which typically begins 2 years after the onset of skin disease. The skin softening can allow a return to clinically normal skin and occurs most commonly on the trunk and upper arms; joint mobility can also improve. In late-stage SSc the skin may become atrophic and feel thinner, particularly over the fingers, dorsum of the hand, and lower legs. Although it is softer at this stage, it may still be tethered to underlying fibrotic tissue, particularly over the fingers.

The modified Rodnan skin score is a method for grading skin thickness in 17 body areas (Fig. 142.9) and is a validated tool used in clinical trials with small interobserver variability.¹⁸ The score in each area ranges from 0 to 3, with 0 representing normal skin and 3 representing taut or hide-bound skin. A score of 1 indicates mild skin thickening and a score of 2 is consistent with a greater degree of skin tautness.^{19,20} The rate of progression of skin thickening, or the skin thickness progression rate, is of prognostic importance, and there is evidence that patients who come to the first office visit with a history of rapidly changing skin thickness have both an increased mortality and a higher risk of renal crisis.²¹

Other skin manifestations include telangiectasias, digital pits, and calcinosis. Telangiectasias are dilated capillaries most commonly present on the face (Fig. 142.10), hands (Fig. 142.11), mucosal membranes, and chest. Digital pits are small areas of indentation on the distal finger pads caused by ischemic damage related to Raynaud phenomenon. Subcutaneous calcinosis occurs in both limited and diffuse cutaneous disease but is more common in patients with limited disease, particularly those with an anti-centromere antibody. It most commonly occurs over areas of trauma such as the extensor surfaces of the forearms (Fig. 142.12) and of the finger pads.

Fig. 142.6 Masson trichrome staining for collagen of a digital artery revealing near occlusion of the vessel lumen due to subintimal fibrosis and periadventitial fibrosis.

Fig. 142.7 Nailfold capillaroscopy using a widefield microscope demonstrating (a) normal nailfold capillaries, (b) “slow” phase capillaries most commonly seen in limited cutaneous systemic sclerosis characterized by capillary dilatation, and (c) “active” phase nailfold capillaries typical of diffuse cutaneous systemic sclerosis with capillary dilatation and avascular areas.

Fig. 142.8 Taut smooth skin over the face and reduced oral aperture of a woman with long-standing scleroderma. Furrowing is present around the mouth, along with some facial telangiectasias.

Fig. 142.10 Facial and lip telangiectasias in a woman with systemic sclerosis sine scleroderma.

Fig. 142.9 Total skin score. Semiquantitative estimates by clinical palpation of the extent and severity of scleroderma skin changes. In all cases, the initial areas involved are peripheral and are the most severely affected. The mild skin change on the chest and on the upper arms permits classification of this individual's disease as diffuse scleroderma.

Fig. 142.11 Telangiectasias of the fingers.

Fig. 142.12 Subcutaneous calcifications, calcinosis of the left forearm and elbow with cutaneous ulceration. (From Porta F, Matucci-Cerinic M. A limited cutaneous SSc patient with severe calcinosis and acro-osteolysis. In: Silver RM, Denton CP, editors. Case studies in systemic sclerosis. London: Springer-Verlag; 2011, p. 259-66.)

The calcification may remain subcutaneous or may drain from the skin surface, ulcerate, and/or become infected. The subcutaneous deposits are composed of calcium hydroxyapatite.

The American College of Rheumatology (ACR; formerly American Rheumatism Association) classification criteria for SSc were formerly based on the extent of skin involvement, presence of digital pits, and/or radiographic evidence of basilar pulmonary fibrosis.²² It was clear that many patients with disease fell within the spectrum of SSc without meeting the prior ACR classification criteria, thus the ACR and European League Against Rheumatism (EULAR) revised the classification criteria for SSc. Skin thickening proximal to the metacarpophalangeal joints sufficiently classifies a patient with SSc; however, for those patients with lesser involvement of the skin, there are seven other factors that are weighted to help classify a patient as having SSc. These factors include digital pits/digital ulcers, telangiectasias, nailfold capillary abnormalities, Raynaud phenomenon, pulmonary hypertension, interstitial lung disease, and scleroderma autoantibodies. Use of the new classification criteria enhances the sensitivity and specificity to 0.91 and 0.92, respectively, compared with the prior classification criteria sensitivity and specificity of 0.75 and 0.72, respectively, for the validation sample described.^{22a}

SYSTEMIC FEATURES

Gastrointestinal involvement

Gastrointestinal involvement, nearly universal in patients with SSc, often manifests as the first non-Raynaud phenomenon symptom. Gastrointestinal manifestations may be mild or severe and occur in patients with limited or diffuse disease. Even in the absence of symptoms, patients with SSc demonstrate motility abnormalities on functional testing. The entire gastrointestinal tract may be involved from the oropharynx to the anus. Secondary Sjögren syndrome may also contribute to abnormal deglutination and swallowing.

The cause of gastrointestinal manifestations relates to smooth muscle atrophy, to which both microvascular insufficiency and neurogenic factors contribute. Smooth muscle atrophy and fibrosis within the gastrointestinal mucosa play a role in gastrointestinal dysmotility; however, intimal proliferation similar to that seen in other vascular beds also occurs in the gastrointestinal tract.

There may be serious social ramifications for patients with SSc and gastrointestinal involvement, and many patients find it difficult to participate in social events or contributed planning owing to embarrassment and discomfort from gastrointestinal disease. Depression, often present and frequently undiagnosed in SSc, has been shown to correlate significantly with gastrointestinal involvement.²³

Oropharynx

Oropharyngeal involvement includes reduced oral aperture from skin tightening, mandibular atrophy, and a shortened frenulum. Patients with SSc, particularly those with dcSSc, are at increased risk of development of carcinoma of the tongue.²⁴ Xerostomia due to SSc and/or secondary Sjögren syndrome also commonly occurs. Most patients with a complaint of dry mouth do not demonstrate the typical inflammatory infiltrate of Sjögren syndrome on minor salivary gland biopsy but instead have submucosal fibrosis. Mouth-related disability can be formally evaluated using a validated tool, the Mouth Handicap in Systemic Sclerosis scale, which has been shown to relate to global disability assessment using the Health Assessment Questionnaire.^{25,26} Because of the importance and difficulty of adequate oral care, specific recommendations regarding oral care in patients with SSc are available.²⁷

Esophagus

Esophageal dysmotility is present in nearly every patient with SSc owing to involvement of the distal two thirds of the esophagus and sometimes results in symptoms of dysphagia. Reduced lower esophageal sphincter pressure occurs, which causes varying degrees of gastroesophageal reflux and dyspepsia and, in some patients, may result in free reflux of acid and/or gastric contents. Patients experience chronic injury to the esophageal mucosa and increased incidence of Barrett metaplasia.²⁸ Other symptoms include dysphagia secondary to esophageal stricture, early satiety, regurgitation of undigested food, hoarseness, cough, and weight loss. Gastrointestinal bleeding can result from erosive esophagitis, esophageal ulcer, a Mallory-Weiss tear, or mucosal telangiectasia.

Barium esophagography may demonstrate esophageal dysmotility, including loss of primary and secondary peristalsis of the distal esophagus as well as esophageal strictures. Esophageal manometry can be useful to

Fig. 142.13 Watermelon stomach. Endoscopic image of the stomach of a patient with scleroderma who experienced recent gastrointestinal bleeding caused by gastric antral vascular ectasia.

document distal esophageal involvement and reduced lower esophageal sphincter pressure in a patient undergoing evaluation for possible SSc. A 24-hour pH probe can also be helpful in monitoring the efficacy of acid-suppressive therapy. Excessive air in the esophagus, reflecting esophageal dysmotility, is a characteristic finding seen on chest radiography or chest computed tomography (CT). Upper endoscopy is performed to assess for sources of bleeding, strictures, metaplasia, or malignancy.

Stomach

Symptoms of gastric involvement include early satiety, bloating, nausea, emesis, anorexia, and weight loss. Delayed gastric emptying can exacerbate symptoms of gastroesophageal reflux and cause bloating. Early satiety and bloating may cause the patient to reduce caloric intake, which leads to weight loss. Gastrointestinal blood loss may result from mucosal telangiectasia, gastritis, or, in more severe cases, gastric antral vascular ectasia. Gastric antral vascular ectasia, described endoscopically as a watermelon stomach (Fig. 142.13), may lead to occult or large amounts of blood loss requiring multiple transfusions and laser therapy.

Small and large intestines

Intestinal dysmotility also causes bloating and cramping. Patients develop diarrhea alternating with constipation due to intestinal bacterial overgrowth. Occult gastrointestinal blood loss may result from mucosal telangiectasias, which may be difficult to detect endoscopically. Pseudoobstruction is a serious sequela of intestinal dysmotility (Fig. 142.14) and manifests as abdominal pain, bloating, and emesis. Although it is a functional ileus, its presentation mimics that of an anatomic obstruction; conservative management is mandated, and surgical intervention should be avoided if at all possible. Large-intestinal mucosal muscular atrophy may result in wide-mouthed diverticula unique to SSc, typically occurring on the antimesenteric surface. Anorectal involvement due to decreased compliance and reduced anal sphincter tone may result in rectal prolapse and/or rectal incontinence.

Hepatic involvement

The liver is rarely primarily involved in SSc; however, an association exists between primary biliary cirrhosis (PBC) and SSc, and a significant proportion of patients with PBC have an anticentromere antibody.²⁹ Antimitochondrial antibodies occur in SSc patients with coexisting PBC. Patients have jaundice and an obstructive biliary picture characterized by elevated alkaline phosphatase and total bilirubin levels. Elevated transaminase levels most often reflect coincident inflammatory muscle disease rather than true hepatic involvement and may indicate a need for muscle evaluation.

Pulmonary involvement

Lung disease is the leading disease-related cause of mortality. Pulmonary disease most typically includes interstitial lung disease (ILD) and/or

Fig. 142.14 Upright abdominal radiograph of a 51-year-old man with systemic sclerosis and pseudoobstruction with pneumatoxis cystoides intestinalis. (From Mitchell M, Bolster MB, LeRoy EC. Scleroderma and related conditions. *Med Clin North Am* 1997;81:129-49.)

pulmonary arterial hypertension (PAH). Other less common lung manifestations include aspiration pneumonia, pleural disease, obstructive airway disease, endobronchial telangiectasia with hemoptysis, malignancy, alveolar hemorrhage, and cryptogenic organizing pneumonia.³⁰

ILD characteristically begins as basilar pulmonary fibrosis and may be seen in patients with either limited or diffuse skin disease, although it tends to be more common and more severe in patients with dcSSc. Approximately 80% of patients have evidence of pulmonary fibrosis at postmortem examination³¹ or on high-resolution CT scans, although clinically evident disease is present in only approximately 40% of patients.³² Patients are at greatest risk of developing ILD within the first 4 years after SSc onset, and black males in their fifth and sixth decades are at the greatest risk of severe lung disease.³³ The presence of anti-topoisomerase I antibody (anti-Scl-70 antibody) is associated with an increased risk of developing diffuse skin involvement and severe pulmonary fibrosis.³⁴ The presence of an anticentromere antibody or anti-RNA polymerase III antibody is associated with a reduced risk of the development of ILD.^{34,35} Patients with ILD usually have exertional dyspnea and dry cough at presentation. Physical examination reveals late inspiratory basilar crackles without signs of congestive heart failure. A chest radiograph may reveal basilar pulmonary fibrosis but may show normal findings.

Pulmonary function testing (PFT) with spirometry, measurement of lung volumes, and tests of gas exchange is the best screening method for ILD. The most sensitive and earliest change is a reduction in diffusion capacity.³⁶ ILD is typically characterized by a reduction in total lung capacity; a reduced forced vital capacity (FVC) is also indicative of restrictive lung disease in the absence of obstructive airways disease (normal ratio of forced expiratory volume in 1 second to FVC). PFT abnormalities may occur before the onset of clinical symptoms, and a noted reduction in lung volumes should prompt further evaluation for ILD. Absence of dyspnea in some cases may relate to an insidious onset of lung symptoms or to the fact that patients with SSc often limit activity levels due to skin or musculoskeletal manifestations. It is important to detect ILD at its earliest stage to initiate treatment before the occurrence of irreversible lung fibrosis. High-resolution computed tomography (HRCT) of the chest reveals ground-glass opacification that is indicative of active inflammation and/or early fibrosis, often referred to as *alveolitis* (Fig. 142.15).³⁷ HRCT findings also include thickening of the interlobular septa, subpleural nodules, honeycomb appearance, and traction bronchiectasis. The CT findings are highly sensitive for ILD in SSc. PFT and HRCT are the standard of care for detecting ILD in patients with SSc. Goh and colleagues³⁸ have developed a useful algorithm to estimate risk

Fig. 142.15 High-resolution computed tomographic scan of the chest of a patient with systemic sclerosis and alveolitis demonstrating ground-glass opacification, a haziness visualized at the lung periphery.

of progression of restrictive lung disease based on spirometry and HRCT findings, and post-hoc analysis of the Scleroderma Lung Study-1 (SLS-1) supports the notion that response to treatment may be predicted from the results of baseline PFT and HRCT findings.³⁹ Bronchoalveolar lavage, historically performed to evaluate for alveolitis, has largely been replaced by HRCT in patients with SSc and lung disease unless evaluation for pulmonary infection is warranted. However, cytokine analysis of bronchoalveolar lavage fluid may provide useful prognostic information.⁴⁰

Pulmonary vascular disease may occur either as a primary vasculopathy or secondary to underlying cardiac disease, hypoxic ILD, or, rarely, chronic thromboembolic disease. Patients with pulmonary hypertension most commonly have dyspnea and/or fatigue at presentation. Atypical chest pain, lower extremity swelling, lightheadedness, and syncope are late symptoms of pulmonary hypertension. Isolated pulmonary artery hypertension (PAH) more commonly occurs in patients with lcSSc, typically presenting many years after the onset of Raynaud phenomenon; however, patients with dcSSc can also manifest isolated PAH occurring relatively early in the disease course.⁴¹ Black patients develop pulmonary hypertension at a younger age than white patients.⁴²

Physical examination findings may include an accentuated P₂ component of the second heart sound (S₂) with or without fixed splitting of S₂. A right-sided S₃ may be present with other signs of right-sided heart failure. Findings of right-sided heart strain on physical examination are not sensitive but, if present, are likely indicative of advanced pulmonary hypertension.

The initial evaluation of the SSc patient with dyspnea should include spirometry with measurement of lung volumes and diffusion capacity. A patient with isolated PAH will demonstrate a reduced carbon monoxide diffusion capacity (DLCO) in the presence of normal lung volumes.⁴³ A declining DLCO may be an early predictor of the development of PAH.⁴⁴ A ratio of FVC to DLCO (FVC% predicted/DLCO% predicted) of more than 1.6 may also be predictive of the presence or development of PAH (mean pulmonary artery pressure of 25 mm Hg or more).⁴⁵ An isolated reduction of DLCO below 40% is predictive of increased mortality,⁴⁶ and the low DLCO may be observed years before the clinical diagnosis of PAH.⁴⁴ An isolated reduction in DLCO may, however, indicate either early ILD, emphysema, or the presence of pulmonary vascular disease; thus two-dimensional Doppler echocardiography and/or HRCT should also be performed.

Echocardiography, although imperfect, is a noninvasive screening tool for detecting pulmonary hypertension (Fig. 142.16).⁴⁷ Pulmonary hypertension can be a difficult disease manifestation to discover, and between 13% and 23% of patients with SSc may have undetected pulmonary hypertension, depending on the threshold value used for its diagnosis (e.g., estimated peak right ventricular systolic pressure [PRVSP] of 30, 35, or 40 mm Hg).^{48,49} Unlike a reduced DLCO, an abnormal PRVSP has not been associated with the future development of pulmonary hypertension, because a PRVSP that is elevated to more than 35 mm Hg has been found, on repeat testing, to be normal in up to 50% of patients 3 years later.⁴⁵ A PRVSP of 40 mm Hg or more by echocardiography has been correlated with reduced exercise tolerance, and a PRVSP of more than 50 mm Hg has been associated with right

Fig. 142.16 Echocardiographic images for a woman with limited cutaneous systemic sclerosis and pulmonary arterial hypertension. (a) Parasternal long-axis view shows left ventricle, dilated right ventricle, and presence of both a left pleural and pericardial effusion. (b) Parasternal short-axis view demonstrating the D-shaped septum seen with pressure overload of the right ventricle. The right ventricle is dilated and again visible is a moderate-sized pericardial effusion. (c) Apical three-chamber view showing dilated right-sided chambers and a pericardial effusion. (d) Continuous-wave Doppler image of tricuspid valve regurgitation with an estimated peak right ventricular systolic pressure of 141 mm Hg plus right atrial pressure.

ventricular enlargement.⁴⁸ A high index of suspicion for pulmonary hypertension is imperative to permit early detection and, in particular, diagnosis before the development of right-sided heart failure. Functional changes in the right ventricle are indicative of both the chronicity and severity of pulmonary hypertension.

Assessment of serum brain natriuretic peptide (BNP), a marker of all-cause myocardial involvement, can be helpful in the evaluation of a patient with possible right ventricular strain. An elevated BNP level has a sensitivity of 56% and a specificity of 95% for detection of pulmonary hypertension and portends a worse prognosis. Additionally, occurrence of a BNP increase in patients being treated for pulmonary hypertension has been associated with worsened survival.⁵⁰

When clinical or echocardiographic findings raise suspicion of pulmonary hypertension, right-sided heart catheterization should be performed to definitively confirm the presence of PAH, rule out other causes of pulmonary hypertension such as diastolic dysfunction, and guide therapeutic interventions. A mean pulmonary artery pressure of 25 mm Hg or more with a normal pulmonary capillary wedge pressure is consistent with PAH.

The 6-minute walk test is also used to follow patients with PAH and provides information regarding a patient's ability to maintain blood oxygen saturation as well as a functional measure of distance walked to follow efficacy of therapies. However, the 6-minute walk test has limitations in patients with SSc who have pulmonary hypertension, because factors aside from dyspnea, such as muscle weakness or lower extremity discomfort, may limit performance; thus musculoskeletal or vascular features of a patient's disease should be considered.⁵¹

Another tool useful in the evaluation of the patient with PAH is cardiac magnetic resonance imaging (MRI). Cardiac MRI provides three-dimensional projections allowing improved visualization of right ventricular mechanics,

such as ventricular volume and mass, as well as an assessment of the pulmonary circulation. Cardiac MRI detects PAH more accurately than does echocardiography and provides additional information on right ventricular function.⁵²

In patients with known ILD, worsening of symptoms may reflect the presence of secondary pulmonary hypertension, warranting evaluation for pulmonary vascular disease and potentially provision of additional therapies for pulmonary hypertension. Patients with SSc and pulmonary hypertension secondary to underlying ILD have a worse prognosis than patients with ILD without pulmonary hypertension.³² Superimposed pulmonary hypertension may accelerate the patient's need for oxygen supplementation, provide an indication for anticoagulation with warfarin, and/or prompt the need for vasodilator therapy.

The presence of PAH historically has predicted extremely high mortality (Fig. 142.17),⁵³ but new treatment options have improved survival.⁵⁴⁻⁵⁷ The use of potent vasodilators in patients with SSc-PAH has demonstrated a 1-year survival of 78% compared with 45% 1-year survival rates among historical controls. Similarly, a survival advantage has been noted in treated SSc patients with exercise-induced PAH, who show a 3-year survival of 86%. The lowest survival rate has been reported in SSc patients with pulmonary hypertension secondary to underlying ILD, with an estimated 28% surviving at 3 years. Factors associated with a worse prognosis in SSc-PAH include age older than 70 years, higher World Health Organization functional class (class III or IV), and higher mean right atrial pressure or pulmonary vascular resistance. Although the best survival has been observed in patients with exercise-induced PAH or low WHO functional class, this likely represents an earlier stage of disease development in these patients. Early aggressive therapy is warranted because even mortality rates in early disease are not negligible.⁵⁸

Fig. 142.17 Survival of patients with systemic sclerosis (SSc) with and without lung involvement. The highest survival rate is among SSc patients without lung disease (top line). The middle line shows survival of patients with SSc and interstitial lung disease, and the lowest survival curve is for SSc patients with pulmonary hypertension (pulmonary hypertension).

Cardiac involvement

Cardiac involvement in SSc, although commonly seen at postmortem examination, is clinically variable and may be subtle in presentation.³¹ The clinical presence of cardiac involvement is predictive of a poorer prognosis.⁵⁹ Cardiac manifestations include pericardial disease, dilated cardiomyopathy, autonomic neuropathy,⁶⁰ and arrhythmias. Left or right ventricular diastolic dysfunction has become a more commonly recognized abnormality, and left ventricular dysfunction may be an important component of pulmonary hypertension.^{61,62}

Patients with SSc and cardiac involvement may have symptoms commonly associated with pulmonary involvement, including dyspnea, palpitations, chest pain, or dizziness. It is important to maintain a high index of suspicion for the possibility that cardiac disease may be contributing to these symptoms.

Pericardial disease can manifest as either pericarditis or, more commonly, as a pericardial effusion. Pericardial effusions, typically exudative if secondary to SSc, accumulate slowly so that pericardial tamponade is a rare occurrence. The echocardiographic presence of small to moderate-sized pericardial effusions is not uncommon in SSc, although typically is not of much clinical significance. The gold standard for detecting pericardial disease is two-dimensional echocardiography, but pericardial involvement can also be found on chest CT or cardiac MRI. Pericardial disease can involve a fibrinous pericarditis with adhesions and inflammatory cell infiltrate^{31,63} or uremic pericarditis in patients with scleroderma renal crisis. The presence of a pericardial effusion, a more common manifestation in patients with dcSSc, is a risk factor for the development of scleroderma renal crisis.⁶⁴ Pericardial effusions have been found with increased incidence in patients with SSc-ILD with echocardiographic evidence of pulmonary hypertension (RVSP of more than 35 mm Hg).⁶⁵

Patients with SSc can develop left or right ventricular systolic dysfunction; it is usually a late occurrence in the disease course, typically has an insidious onset, and most commonly is seen in patients with dcSSc. The presence of congestive heart failure has been associated with increased mortality in patients with SSc. Measurement of serum BNP level is also helpful in evaluating and following patients with reduced ventricular function. For patients with significant left ventricular systolic dysfunction, implantation of an automatic defibrillator should be considered using the guidelines for patients with cardiomyopathy of other causes.

Pathologic changes of the myocardium identified in postmortem studies include myositis and fibrosis (Fig. 142.18).⁶³ Additionally, patchy myocardial fibrosis occurs with contraction band necrosis, which increases the risk of conduction abnormalities. Patchy myocardial fibrosis likely occurs as a response to ischemic-reperfusion insult from microvascular involvement. Patients who have an overlap syndrome with inflammatory myositis are more likely to develop myocarditis and present acutely with a dilated

Fig. 142.18 Photomicrograph showing lymphocyte and plasma cell infiltration of the myocardium as well as fibrosis (hematoxylin-eosin, ×10). These changes are largely related to an associated fibrinous pericarditis in this young woman with scleroderma.

cardiomyopathy as a manifestation of underlying muscle disease. Endomyocardial biopsy can demonstrate inflammatory changes with or without fibrosis.

Diastolic dysfunction may occur in patients who have essential hypertension. Additionally, there seems to be a predilection for the development of either right or left ventricular diastolic dysfunction in SSc, and this may reflect myocardial fibrosis and reduced ventricular compliance. Left ventricular diastolic dysfunction appears to occur with greater frequency than systolic dysfunction⁶¹ and is present to a higher extent in patients with pulmonary hypertension.⁴² Diastolic dysfunction may contribute significantly to the presence of pulmonary hypertension (venous rather than arterial) or, on the contrary, right ventricular diastolic dysfunction may result from PAH in this patient population.

Atherosclerotic coronary artery disease appears to occur at an increased rate in patients with SSc, and postmortem studies reveal lesions that involve most commonly the small coronary arteries or arterioles.^{31,66,67} Perfusion defects noted on nuclear medicine testing also occur commonly. Additionally, cardiac “Raynaud phenomenon,” or cold-induced and reversible vasospasm, has been reported.^{68,69} The presence of defects on thallium scanning is predictive of a poorer prognosis and reflects more severe myocardial involvement.

Fibrosis along conduction pathways may cause arrhythmias. Patients may experience transient palpitations or more significant symptoms. Objective testing may be of low yield owing to the fleeting nature of many conduction abnormalities; however, changes may be detected with electrocardiography, Holter monitoring, or longer-duration event monitoring. The conduction defects most commonly found on electrocardiography include a prolonged PR interval, left anterior fascicular hemiblock, and intraventricular conduction delays. The most common finding on rhythm analysis is premature ventricular contractions.⁷⁰ Premature atrial contractions also occur commonly. Additional rhythm disturbances may include multifocal atrial tachycardia or supraventricular tachycardia. Atrioventricular defects or the more lethal rhythms such as ventricular tachycardia are much rarer. Rhythm disturbances occur more commonly in patients with dcSSc, and their presence portends a poorer prognosis.

Echocardiography is a valuable noninvasive method for evaluating cardiac function, providing information about chamber sizes, wall motion abnormalities, and contractility. Pulsed tissue Doppler echocardiography provides additional information about cardiac function in the longitudinal plane, and the subendocardial fibers, mostly longitudinal in orientation, are those affected most by microvascular ischemia. Longitudinal systolic and diastolic abnormalities are often the first signs of cardiac involvement in SSc heart disease.⁷¹

Cardiac MRI has become a useful noninvasive tool in patients with SSc, providing high spatial resolution of the heart with small interobserver and intraobserver variability, and it permits evaluation of ventricular function, mass, and size. It is particularly helpful for assessing the right ventricle. The myocardium may show evidence of changes consistent with fibrosis, with late gadolinium enhancement indicating diffuse fibrosis. Small subendocardial defects may relate to small-vessel ischemic injury.^{70,72} Cardiac MRI permits assessment of perfusion to better evaluate microvascular ischemia and response to therapies.⁷⁰⁻⁷²

Single-photon emission computed tomography (SPECT) evaluates myocardial perfusion and is another method allowing evaluation of function (left ventricular ejection fraction) and wall motion abnormalities. Additionally,

Fig. 142.19 Vascular changes characteristic of systemic sclerosis. This renal arteriole demonstrates endothelial proliferation, medial hypertrophy, and adventitial fibrosis in a patient with scleroderma renal crisis (hematoxylin-eosin).

there is evidence for the usefulness of gated myocardial perfusion SPECT for evaluating early changes in diastolic function in patients with SSc.⁷³

Renal involvement

Scleroderma renal crisis (SRC), one of the cardinal vascular manifestations of SSc, is characterized by neither an inflammatory process nor evidence of glomerulonephritis. SRC is a high-renin state, and the pathologic changes in the blood vessels are similar to those seen in other vessels in patients with SSc (Fig. 142.19). Plasma measures of renin are not, however, predictive of the development of SRC.

Before the advent of angiotensin-converting enzyme (ACE) inhibitors, renal involvement was the leading cause of death in SSc. SRC still occurs; however, with early recognition and aggressive management the outcome is much improved. It is estimated that 10% of patients with SSc will develop SRC, which occurs almost exclusively in patients with dcSSc and develops within the first 3 years of disease.^{74,75} Risk factors for SRC include diffuse skin involvement, tendon friction rubs, anti-RNA polymerase III antibody, new-onset anemia, and pericardial effusion. Nonmalignant hypertension, urine sediment abnormalities, and antibodies to topoisomerase I or centromere are not predictive of SRC. Males, those developing the disorder at an older age, and those with a serum creatinine concentration of more than 3 mg/dL have the poorest outcome.

SRC classically presents with new-onset hypertension. The heralding sign of the increased blood pressure may range from a mild increase in a patient who typically has a low blood pressure to a marked elevation of the blood pressure. Associated signs and symptoms are similar to those seen in malignant hypertension and may include dyspnea, headache, visual disturbances, seizure, pulmonary edema, lower extremity edema, and fundoscopic changes. The presentation of SRC can be identical to that of malignant hypertension, and the proper identification of the patient as having SSc is imperative so that appropriate therapy with ACE inhibitors can be instituted. More than one half of cases of SRC require dialysis; however, many patients can discontinue dialysis within 2 years. It is thus essential that patients continue to receive ACE inhibitors even if renal insufficiency develops, because the disease can correct or be reversed even late into the renal course. Occasionally, SRC presents before the onset of skin changes, which makes the appropriate identification of the patient's disorder and his or her management more challenging.

SRC is characterized by a microangiopathy with anemia and schistocytes on peripheral blood smear, along with thrombocytopenia, renal insufficiency, proteinuria, and active urinary sediment. At presentation SRC may be confused with thrombotic thrombocytopenic purpura, particularly in patients with seizures. Although thrombotic thrombocytopenic purpura may rarely occur in SSc, it is imperative that the diagnosis of SRC be made and ACE inhibition initiated. There is no known role for plasma exchange in the management of SRC.

A variant of SRC termed *normotensive SRC* is characterized by the typical laboratory abnormalities of SRC in the presence of a normal blood pressure and may progress to renal insufficiency and/or the need for dialysis. Normotensive renal crisis occurs most typically in patients who have previously been treated with glucocorticoids, particularly a prednisone dosage (or its equivalent) of more than 15 mg daily.⁷⁶

Renal insufficiency may also occur in patients with an overlap of SSc and systemic lupus erythematosus (SLE) and be caused by an immune-mediated process such as occurs in patients with SLE. Also, cases of antineutrophil

Fig. 142.20 Baseline musculoskeletal sonogram of the second metacarpophalangeal joint. Power Doppler ultrasonography shows positive results with synovial hypertrophy plus effusion. (From Valentini G, Cuomo G, D'Abrascia V, Cappabianca S. A scleroderma patient with swollen and tender joints of both hands. In: Silver RM, Denton CP, editors. *Case studies in systemic sclerosis*. London: Springer-Verlag; 2011, p. 239-50.)

cytoplasmic antibody-associated vasculitis have been reported in SSc and should be considered as an overlap condition with SSc because these patients may have a renal-pulmonary syndrome in addition to SSc.⁷⁷⁻⁷⁹ If an alternative cause to SRC for renal insufficiency is being considered, then renal biopsy may be useful; otherwise, renal biopsy is not necessary to diagnose SRC.

Musculoskeletal involvement

Musculoskeletal symptoms are very common in SSc. The earliest symptoms attributable to scleroderma are arthralgia and myalgia; some patients may develop a true inflammatory arthropathy and/or myopathy. The joints most commonly involved are the PIP, MCP, wrist, and ankle joints. Because of overlying skin thickening it may be difficult to appreciate the presence of joint swelling. Musculoskeletal ultrasonography may be useful in such instances (Fig. 142.20). Progressive skin changes can also cause joint flexion contractures, and these can result in significant debilitation.

Tendon friction rubs are a palpable physical examination sign overlying tendon sheaths, commonly occurring at the finger, wrist, elbow, knee, and/or ankle joints. Tendon sheath discomfort occurs due to inflammation and fibrosis (Figure 142.21). Tendon friction rubs are predictive of dcSSc and are manifest in approximately one third of such patients.

Muscle weakness and generalized fatigue are prominent symptoms. Many patients develop muscle weakness as a result of deconditioning and joint flexion contractures. Proximal muscle weakness may be related to one or more causes; for example, a bland myopathy due to muscle fibrosis or an overlap syndrome of SSc with polymyositis or dermatomyositis with a true inflammatory myopathy. Patients with the latter may test positive for anti-PM-Scl antibody, which is seen more commonly in whites.⁷⁵ The bland myopathy associated with SSc is characterized by a mild increase in creatine kinase level and may or may not show inflammatory changes on electrodiagnostic testing. In some patients, the creatine kinase value is normal but levels of other muscle enzymes (e.g., aldolase) may be elevated. Muscle biopsy generally does not reveal an inflammatory infiltrate. The overlap of SSc with an inflammatory myopathy is, however, characterized by elevated muscle enzyme levels and evidence of inflammatory changes on both electromyography and muscle biopsy.

PSYCHOLOGICAL HEALTH

Patients with SSc often have symptoms of poor psychological health. It has been estimated that nearly 50% of patients have mild depressive symptoms and approximately 17% have moderate to severe depression.⁸⁰ A relationship exists between depression and self-rated disability,⁸⁰ decreased functional status,²³ upper and lower gastrointestinal symptoms,^{23,81} unmarried status,⁸¹ and lower levels of education.^{23,81} Fatigue, chronic pain, and altered personal appearance likely also contribute to depressive symptoms. Each of these symptoms and findings is associated with a poor health-related quality of life. The Center for Epidemiologic Studies Depression Scale is a validated screening tool used to assess for depressive symptoms in patients with SSc.⁸² Clinicians who care for patients with SSc should be highly concerned about the likelihood of depression in their patients, and routine screening is recommended.

Fig. 142.21 Proton-density fat-saturated magnetic resonance image demonstrating fluid surrounding the posterior tibial and peroneal tendons (arrows). (From Khanna D, Khanna PP. A 54-year old woman with pain and stiffness of hands and tendon friction rubs. In: Silver RM, Denton CP, editors. London: Springer-Verlag; 2011, p. 271. Courtesy Dr. T. Pope, Medical University of South Carolina.)

SEXUAL FUNCTION

Sexual dysfunction occurs in both men and women with SSc. Erectile dysfunction occurs in up to 80% of men with SSc and typically begins approximately 3 years after disease onset.⁸³ A reduction in penile blood flow contributes to erectile dysfunction and is due to both endothelial changes in small arteries and corporal fibrosis from excessive collagen deposition.⁸⁴ Altered penile blood flow occurs in the absence of atherosclerotic disease in SSc. Sexual function assessments can be performed by patient interview and enhanced by using a validated questionnaire such as the five-item version of the International Index of Erectile Function.⁸⁵

Sexual dysfunction is less well studied in women with SSc, but patients report symptoms of vaginal dryness, dyspareunia, and vaginal ulcerations, more so after disease onset than before disease onset and also more than patients with other autoimmune diseases.⁸⁶ A significant relationship has been found between sexual dysfunction and gastroesophageal reflux and skin tightness in women with SSc. Decreased libido and decreased number and intensity of orgasms are also reported. Women with SSc experience an early menopause compared with control subjects. It is important for clinicians to consider sexual dysfunction in the health-related quality of life evaluation of patients with SSc.

SYSTEMIC SCLEROSIS SINE SCLERODERMA

Systemic sclerosis sine scleroderma is a variant of SSc in which the patient has many features of SSc in terms of visceral and/or serologic involvement; however, there is no apparent skin thickening. Such patients nearly always have symptoms of Raynaud phenomenon and test positive for antinuclear antibody (ANA), and they may demonstrate digital pits, telangiectasia, gastroesophageal reflux disease, pulmonary fibrosis, and/or pulmonary hypertension. Results of nailfold capillaroscopy are also typically abnormal, revealing capillary dilatation without avascularity, or the slow phase, typical of patients with lcSSc.

SEROLOGIC FEATURES

Scleroderma is an autoimmune disease characterized by the presence of several autoantibodies. Most patients have a positive ANA test result and, in fact, negativity for ANA is associated with a more severe disease course. It should be noted that many commercial laboratories use immunoassay methods for the detection of ANA, and such assays may yield a relatively high rate of false-negative results on sera of SSc patients. When SSc is suspected it is important to order ANA testing by indirect immunofluorescent assay, preferably using HEp-2 cells as substrate. A truly negative ANA test result in a patient with skin thickening should lead the clinician to consider one of the many causes of pseudoscleroderma, including diffuse fasciitis with eosinophilia, nephrogenic systemic fibrosis, scleromyxedema, sclerodema, and other disorders discussed in Chapters 147 and 170. Alternatively, in the presence of SSc and a negative ANA result a paraneoplastic presentation of SSc should be considered and careful age-appropriate and symptom-related malignancy screening should be performed.

In SSc, the immunofluorescence ANA most commonly has a nucleolar pattern. Positivity for anticentromere antibody is generally seen in patients with lcSSc (20% to 40%). Positivity for anti-Scl-70 antibody is associated with dcSSc and increased risk for the development of ILD. Patients who have an anti-RNA polymerase III antibody have a worse prognosis, show extensive skin thickening with increased frequency of tendon friction rubs, and are more likely to develop SRC, although they have a lower incidence of ILD.^{35,87} The Th/To antibody is associated with lcSSc and pulmonary hypertension, although patients with this autoantibody also may manifest ILD or SRC.⁸⁸ U11/U12-RNP antibody is associated with ILD, often severe; however, tests for this antibody are not yet available for commercial use.⁸⁹

MALIGNANCY

SSc has an increased association with certain malignancies, and as with other autoimmune diseases, it can present as a paraneoplastic syndrome, the latter being associated with a more severe or refractory disease course.⁹⁰ SSc patients, particularly those with underlying pulmonary fibrosis, have an increased risk of lung cancer.^{91,92} As for non-SSc patients who have pulmonary fibrosis, there is an increased risk of development of lung adenocarcinoma. There is some evidence suggesting an increased risk of breast cancer in patients with SSc, but the issue is controversial. Others have found a temporal relationship between the onset of SSc and the diagnosis of breast cancer, although the actual incidence of breast cancer may not be increased.^{92,93} Patients with chronic gastroesophageal reflux are at increased risk of development of Barrett metaplasia, and this then may increase the risk of developing adenocarcinoma of the esophagus.

The treatment of some malignancies requires consideration of irradiation. Historically there have been great concerns about the use of radiation to treat patients with SSc because of the resulting skin fibrosis that can occur after therapy. Newer treatments including implantable radiation pellets do not seem to pose additional risk.

Etiology and pathogenesis of systemic sclerosis

■ JOHN VARGA ■ ROBERT LAFYATIS

- Systemic sclerosis (SSc) is an acquired chronic connective tissue disease characterized by autoimmunity, vascular damage, and tissue fibrosis.
- The cause of SSc is unknown.
- Multiple genes contribute to risk for SSc, but their effects are modest.
- Vascular injury is an early and primary event that results in obliteration of multiple small vessels and consequent tissue hypoxia.
- Specific autoimmunity and evidence of innate immunity are prominent in target organs and in serum.
- Interstitial and perivascular fibrosis occurs in the skin, lungs, heart, and other internal organs. Fibrosis in these tissues is resistant to therapy and contributes to morbidity and mortality.

INTRODUCTION

The cause of systemic sclerosis (SSc) is unknown, but environmental influences and multiple genetic factors contribute to disease susceptibility and clinical manifestations. The pathogenesis of SSc encompasses interrelated yet distinct vascular, inflammatory, and fibrotic processes. Although inflammation and autoimmunity are prominent in early-stage disease and fibrosis and vascular insufficiency dominate in late-stage disease, considerable patient-to-patient variability exists in the relative contribution of these three pathomechanistic processes to the clinical manifestations of SSc.

Investigation using *in vitro* cell culture, *in vivo* disease modeling with genetically engineered strains of mice, genome-wide gene expression profiling, proteomics and transcriptomics, and the application of “systems biology” approaches is yielding an integrated picture of pathogenesis by annotating the cell types, signaling pathways, molecules, genes, and epigenetic markers that are deregulated in SSc. Injury in genetically predisposed individuals causes endothelial cell perturbation, vascular damage, and concurrent activation of both the innate and adaptive immune systems. Recurrent or sustained injury results in persistent immune responses and progressive obliterative vasculopathy with consequent tissue hypoxia in multiple organs. In some patients, unchecked activation of fibroblasts leads to excessive accumulation of collagen and extracellular matrix (ECM) molecules. Differentiation of bone marrow–derived mesenchymal progenitor cells and resident fibroblasts, pericytes, and vascular cells into biosynthetically active myofibroblasts further exacerbates the fibrogenesis. Over time, vascular insufficiency, tissue fibrosis, and matrix rigidity disrupt the architecture of affected organs and result in their failure. The progressive and intractable nature of these pathogenetic processes accounts for the poor prognosis of patients with SSc.

ETIOLOGY

Multiple genetic factors contribute to disease susceptibility. The etiology of SSc is unknown, although small studies have implicated infections, environmental exposures, occupational factors, and drugs as potential risk factors.

Defining the genetic contribution to systemic sclerosis

The contribution of genetic background to SSc risk is uncertain. One informative study examining the relative risk for SSc in first-degree family members and siblings indicated a 13- and 15-fold increase, respectively. In addition, certain ethnic groups have an increased prevalence of SSc. Despite these familial and ethnic associations, twin studies have not confirmed a strong genetic basis for familial and ethnic aggregation.

A recently completed GWAS analysis confirmed the major histocompatibility complex (MHC), as well as IRF5, and STAT4 gene regions as genetic risk factors for SSc.¹ Additional genetic loci identified in this GWAS included IRF4, CDH7, and CD247. The CD247 locus encodes a T-cell receptor subunit that participates in regulation of the immune response and could have a direct role in the pathogenesis of SSc. It is notable that the HLA region, STAT4, and IRF5 loci encode proteins involved in immune responses, and variants at these loci are also associated with other autoimmune conditions. This lends support for the concept of shared pathogenetic drivers of SSc and other autoimmune diseases and highlights a strong autoimmune component underlying the pathogenesis of SSc.

Gene expression in systemic sclerosis: distinct molecular subsets

Application of comprehensive genome-wide profiling of gene expression has led to the emergence of new paradigms of disease classification. The two major clinical patterns of SSc, limited and diffuse cutaneous disease, can readily be distinguished by using clustering software that looks for patterns of altered gene expression in skin from patients with SSc.¹ This “unsupervised clustering” of an identified “intrinsic classifier” set of genes shows further disease heterogeneity at the molecular level (Fig. e143.1). Best defined is the division of patients with diffuse cutaneous SSc into two subgroups based on the expression of distinct gene clusters that prominently include gene expression “signatures” indicative of proliferation or inflammation. These molecular disease subgroups appear to be stable over time, thus suggesting that they represent underlying disease heterogeneity rather than simply different stages of the same process. Molecular heterogeneity in SSc might underlie the observed differences in clinical manifestations, rates of progression, and responsiveness to therapies. Gene profiling of lesional tissue might also be a sensitive tool for detecting the effects of treatment.

Infectious agents

Although infectious agents have long been suspected as being triggers in SSc, no infection has convincingly been linked to pathogenesis. A “pan-bacteria” polymerase chain reaction–screening approach found no evidence of persistent bacterial infection in the skin in 18 patients with SSc. Some patients with SSc have serum antibodies directed against the UL83 and UL94 protein epitopes of human cytomegalovirus (hCMV). Anti–topoisomerase I antibodies can cross-react with hCMV-derived proteins, thus suggesting molecular mimicry as a mechanism linking hCMV infection and SSc. Because antibodies to UL94 can activate fibroblasts and induce endothelial cell apoptosis *in vitro*, the anti-CMV immune response might have a causative role in vascular damage and fibrosis. In addition, infection with CMV has been implicated in allograft vasculopathy, a common complication of solid organ transplantation characterized by neointima formation and smooth muscle proliferation, similar to the obliterative vasculopathy of SSc, and can stimulate the synthesis of CTGF (CCN2). Human parvovirus B19 infection has also been documented in some cases of SSc.

Genetic contributions

Several associations have been reported when using a target gene approach. Early studies showed relatively weak associations with DRB1*11 and DRB1*0301. However, other studies have suggested that this is actually due to an association with HLA-DQA1*0501, which is in linkage disequilibrium with DRB1*11 and DRB1*0301. A C→T missense single nucleotide polymorphism (SNP) in *PTPN22*, which is associated with a variety of related autoimmune diseases, was seen more frequently in some studies in SSc patients. An SNP in *IRF5*, another gene associated with autoimmune diseases such as systemic lupus erythematosus (SLE) and Sjögren syndrome, has recently been associated with SSc. Replication cohorts have failed to confirm certain SSc associations with candidate genes. A prominent example is an SNP in the promoter region of the gene for connective tissue growth factor (CTGF). In another example, SSc-associated polymorphisms in *SPARC*, identified through microarray studies of fibroblasts from SSc patients, were not confirmed in a subsequent study. Potential explanations for such discrepancies might include ethnic differences in the cohorts studied. The assembly of large DNA banks from patients with SSc and control subjects is now permitting rapid confirmation or rejection of genetic associations. Whole exome sequencing and genome-wide association studies (GWASs) making use of large DNA repositories should clarify important genetic associations in SSc.

BOX 143.1 ENVIRONMENTAL AGENTS AND DRUGS POTENTIALLY IMPLICATED IN TRIGGERING SCLERODERMA-LIKE SYNDROMES

Chemicals	Drugs
Silica	Bleomycin
Heavy metals	Pentazocine
Mercury	Taxol
Organic chemicals	Cocaine
Vinyl chloride	
Benzene	Dietary supplements/appetite suppressants
Toluene	L-Tryptophan (contamination)
Trichloroethylene	Mazindol
	Fenfluramine
	Diethylpropion

Environmental exposure, drugs, and radiation

The occurrence of temporal or geographic clusters suggests shared environmental exposures causing disease. Epidemiologic investigations have generally failed to substantiate putative clusters of SSc. In contrast, well-documented outbreaks of SSc-like illnesses have been reported. As an example, the toxic oil syndrome in Spain was linked to the ingestion of contaminated rapeseed cooking oil. Contaminated lots of L-tryptophan dietary supplements were implicated in the epidemic of eosinophilia-myalgia syndrome (EMS) in 1989, although the precise identity of the contaminant was never fully established. Even though the EMS epidemic largely subsided after withdrawal of dietary L-tryptophan from the market, sporadic cases continue to occur.² Recently, exposure to certain gadolinium-containing radiologic imaging dyes was implicated in causing nephrogenic fibrosing syndrome in patients with chronic kidney disease. Scleroderma-like skin induration, with or without multisystem involvement and evidence of autoimmunity, is prominent in each of these toxicoepidemic syndromes; however, clinical, histopathologic, and laboratory features readily distinguish them from SSc. Men with exposure to silica or working in construction-related occupations have an increased incidence of SSc. Other occupational exposures involve polyvinyl chloride, trichloroethylene, and organic solvents. Anecdotal reports allege an association between SSc and exposure to pesticides, hair dyes, and industrial fumes.

Drugs implicated in SSc-like illnesses include the chemotherapeutic agent bleomycin, as well as pentazocine and cocaine. Use of appetite suppressants has been linked to the development of pulmonary arterial hypertension (PAH). An apparent increase in SSc incidence in women who underwent silicone breast augmentation raised alarm regarding a causal association. Large-scale epidemiologic surveys, however, failed to confirm increased risk for connective tissue diseases associated with breast implants. Radiation treatment of malignant neoplasms has been linked to both *de-novo* SSc and exacerbation of preexisting SSc. Some of the environmental agents and drugs potentially associated with SSc are listed in [Box 143.1](#).

PATHOLOGY

The two pathologic hallmarks of SSc are obliterative microvasculopathy and interstitial/vascular fibrosis in multiple organs.³ Infiltration of target organs by inflammatory cells is often seen in early-stage disease, particularly around blood vessels. In the skin, the infiltrates are composed primarily of CD4+ lymphocytes and monocytes ([Fig. 143.1](#)), whereas CD8+ lymphocytes predominate in the lungs.

Vascular pathology

Vascular injury and endothelial cell activation are the earliest—and possibly primary—pathogenetic events in SSc. Histologic evidence of vascular damage precedes fibrosis and can be detected in clinically affected as well as unaffected skin. Expansion of the intimal layer in small and medium-sized arteries ([Fig. 143.2](#)) is a striking pathologic finding that SSc shares with chronic allograft arteriopathy. Intimal proliferation is due to myointimal cell proliferation and migration and collagen deposition. The basement membranes are thickened and reduplicated. In addition to structural changes, evidence of impaired fibrinolysis and increased levels of circulating von Willebrand factor are prominent. Endothelial injury causes platelet aggregation with ensuing release of platelet-derived growth factor (PDGF), serotonin, and endothelin-1 (ET-1) and endothelial cell apoptosis. Vasculitis

Fig. 143.1 Inflammatory infiltrate in the dermis. This skin biopsy specimen shows a perivascular mononuclear cell inflammatory infiltrate. Note the expansion of the collagenous reticular dermis, encasement of sweat glands, and loss of subcutaneous adipose tissue (hematoxylin-eosin).

Fig. 143.2 Vascular changes in the myocardium. An intramyocardial artery shows intimal proliferation and marked narrowing of the vascular lumen. Similar findings occur in small arteries in multiple vascular beds. There is also evidence of myocarditis in this specimen, with inflammatory cells located between myocardial cells (hematoxylin-eosin).

or immune complex deposition in vessel walls is uncommon. In advanced SSc, fibrin deposition and perivascular fibrosis cause progressive luminal occlusion. Widespread obliterative vasculopathy of small and medium-sized arteries in multiple vascular beds ultimately results in vascular rarefaction and chronic tissue hypoxia.

Tissue fibrosis

Fibrosis is defined by excessive tissue accumulation of type I collagen and other fibrillar collagens, fibronectin, elastin, cartilage oligomeric protein (COMP), periostin and osteopontin, and proteoglycans such as decorin, fibromodulin, and lumican, as well as matricellular molecules such as SPARC. The process is associated with increased stiffness and loss of compliance of the ECM. Fibrosis disrupts tissue architecture, which results in progressive dysfunction and eventual failure of target organs.

Organ-specific pathologic findings**Skin**

Fibrosis of the skin leads to expansion of the dermis and obliteration of the hair follicles, sebaceous and sweat glands, and other skin appendages.

Collagen fiber accumulation is most prominent in the reticular (deep) dermis and gradually invades the subjacent adipose layer with entrapment of fat cells. Skin biopsy specimens in early stages of SSc may reveal perivascular cellular infiltrates composed of T lymphocytes, monocytes, and less commonly, mast cells⁴ and eosinophils. The number of myofibroblasts, a contractile cell that is intermediate between fibroblasts and smooth muscle cells, is increased in the lesion. With progression of disease, the skin atrophies with thinning of the epidermis, effacement of the rete pegs, and accumulation of compact hyalinized collagen bundles in the dermis (Fig. 143.3). The subcutaneous adipose layer is shrunk or may be completely absent. Evidence of tissue hypoxia because of the paucity of dermal capillaries can be found even in clinically uninvolved “normal” skin.

Lungs

Histologic evidence of lung injury is common in all forms of SSc. The early stages are characterized by patchy infiltration of the alveolar walls by lymphocytes, plasma cells, macrophages, and eosinophils. With disease progression, interstitial fibrosis (Fig. 143.4), often coexisting with vascular damage within the same lesions, predominates. Intimal thickening of the pulmonary arteries, best seen with elastin stain, underlies PAH and at autopsy is

Fig. 143.3 Excess dermal collagen deposition in a patient with established systemic sclerosis. Note the marked thickening and sclerosis of the dermis and scant perivascular inflammatory infiltrates. There is entrapment of cutaneous glands and obliteration of subcutaneous adipose layers (hematoxylin-eosin).

Fig. 143.4 Interstitial lung fibrosis in systemic sclerosis. The alveolar septa is markedly thickened because of the accumulation of connective tissue. An inflammatory cell infiltrate is present. Note the dramatic disruption of normal lung architecture (hematoxylin-eosin).

frequently accompanied by pulmonary emboli and myocardial fibrosis (Fig. 143.5). The most characteristic histologic pattern of SSc lung fibrosis is nonspecific interstitial pneumonitis (NSIP) associated with moderate interstitial inflammation and fairly uniform distribution of fibrosis. Less commonly seen is the usual interstitial pneumonia (UIP) characterized by scattered fibroblastic foci, a pattern is associated with a worse prognosis. Progressive septal thickening impairs gas exchange and contributes to worsening of pulmonary hypertension. Extensive pulmonary fibrosis may predispose to lung carcinoma.

Gastrointestinal tract

Pathologic changes can occur at any level of the gastrointestinal tract from the mouth to the rectum. The esophagus is virtually always affected, with fibrosis in the lamina propria, submucosa, and muscular layers and characteristic vascular lesions. Chronic reflux is often complicated by esophageal inflammation, ulcerations, and stricture formation. Barrett esophagus with metaplasia of the squamous lining of the esophagus into columnar epithelium develops in up to a third of patients.

Kidneys

Acute scleroderma renal crisis is characterized histologically by vascular changes indistinguishable from other forms of malignant hypertension. The most prominent changes occur in the small interlobular and arcuate renal arteries and consist of reduplication of the elastic lamina, marked intimal proliferation, fibrinoid changes, and narrowing and obliteration of the lumen, commonly accompanied by microangiopathic hemolysis and degeneration of tubular cells (Fig. 143.6). A study examining whether renal biopsy findings could predict the outcome of scleroderma renal crisis found that patients with a poor outcome had more extensive vascular thrombosis and glomerular collapse than did those in whom renal function was restored. Scleroderma renal crisis can clinically resemble thrombotic thrombocytopenic purpura (TTP), but in contrast to TTP, the profound reduction in serum levels or activity of von Willebrand factor cleaving protease (ADAMTS-13) does not occur in SSc. The characteristic histologic features of scleroderma renal crisis are illustrated in Figure 143.7.

Heart

Even though only 25% of patients with SSc have clinical evidence of myocardial disease, cardiac abnormalities are found in up to 80% at autopsy. The characteristic myocardial contraction band necrosis is thought to reflect repeated ischemia-reperfusion. Patchy myocardial fibrosis distributed throughout both ventricles is common and often accompanied by cardiac hypertrophy (Fig. e143.2). Significant interstitial and perivascular fibrosis may occur in the absence of clinically evident heart involvement. Skeletal muscle inflammation is frequent in SSc and can be accompanied by acute myocarditis.

Pathologic findings in other organs

Fibrosis of the thyroid glands is common. Broad bands of fibrous tissue are seen, along with atrophy and obliteration of the follicles, in the absence of inflammation. Abnormal thyroid function test results and antithyroperoxidase autoantibodies are frequent. Erectile dysfunction may be an initial manifestation of SSc. Pathologic examination shows extensive proliferative and obliterative changes in the penile blood vessels. Fibrosis of the salivary and lacrimal glands in the absence of inflammation may be associated with Sjögren syndrome. Synovial biopsy specimens show fibrosis and characteristic vascular changes in the small arterioles.

Fig. 143.5 Pulmonary artery lesion. Elastin stain demonstrates intimal thickening (accumulation of matrix on the luminal side of the elastic lamina) in a small pulmonary artery. Note only mild interstitial fibrosis in this specimen from an individual who died of pulmonary hypertension associated with limited cutaneous systemic sclerosis.

Fig. e143.2 Myocardial fibrosis in systemic sclerosis. (a) Note the dramatic increase in perivascular and perimysial accumulation of collagen (blue with the Masson trichrome stain). (b) Fibrosis involving the conducting system, which can cause heart block.

Fig. 143.6 Renal blood vessel in systemic sclerosis. Luminal narrowing is present as a result of intimal proliferation in a renal artery. Note the extensive reduplication of the elastic lamina and concentric layering in the media (onionskin lesion) (elastin stain).

Fig. 143.7 Renal scleroderma. A kidney biopsy specimen shows vascular disease (bottom left and upper right) with luminal narrowing and reduplication of the elastic lamina. One glomerulus (top) shows fibrinoid deposition (darker pink color), indicative of thrombosis.

ANIMAL MODELS

Various experimental manipulations and inbred mouse strains have been studied as models of SSc. None of these putative disease models recapitulates the full extent of the disease attributes listed in Table 143.1, such as the overlapping microvascular/immune/fibrotic pathology, phenotype-specific autoantibodies, temporal and spatial evolution of fibrotic lesions, and progressive multiple-organ damage. Therefore, observations from currently used mouse models of SSc cannot be readily extrapolated to human disease. Contemporary mouse models fall into three categories: (1) spontaneous mutations or genetic manipulations giving rise to mouse strains with heritable scleroderma-like traits, such as skin induration (tight skin mouse [Tsk1], tight skin 2 [Tsk2/+], mice, transforming growth factor- β [TGF- β] receptor transgenic animals); (2) inducible models in which scleroderma is elicited by exposure to chemicals, particularly bleomycin; and (3) transplantation of HLA-mismatched immunocompetent cells resulting in chronic graft-versus-host disease (GVHD) with scleroderma-like skin changes (Table 143.2). Details on the heritable and bleomycin models are presented in the supplementary material.

Immunologic models

Topoisomerase I immunization in mice

Subcutaneous injection of recombinant topoisomerase I in mice results in the time-dependent development of fibrotic changes in the skin and lungs.⁹

TABLE 143.1

Key traits of systemic sclerosis*

Disease attribute	Comment
Disease course	Insidious onset in adults, chronic and generally progressive course; female preponderance
Skin induration	Starts distally in the digits (sclerodactyly), advances centripetally; symmetrical and widespread Early dermal inflammation, followed by fibrosis, most prominent in the reticular dermis Loss of adnexal structures Subcutaneous adipose atrophy Late-stage epidermal thinning, calcinosis cutis
Internal organs	Progressive and irreversible fibrotic damage in the lungs, intestinal tract, heart, and other organs
Vascular involvement	Early vascular endothelial cell activation, microvascular obliterative vasculopathy, subintimal proliferation and perivascular fibrosis, resulting in Raynaud phenomenon, cutaneous telangiectasia, pulmonary arterial hypertension, ischemic digital ulcers
Inflammation/ autoimmunity	Early perivascular infiltration in the skin and lungs by T cells, B cells, monocyte/macrophages; dendritic cells; type 2-skewed immune response; innate immune response; SSc-specific autoantibodies

*An ideal animal model of systemic sclerosis should recapitulate some or all of these features.

Fibrosis develops only when the antigen is administered together with complete Freund adjuvant, which is required to generate a strong IL-6 response; indeed, IL-6–null mice were resistant to fibrosis. Circulating antibodies to topoisomerase I develop in topoisomerase I-immunized mice. This novel mouse model recapitulates a scleroderma-specific antigen driving diffuse fibrosis and autoimmunity.

Type V collagen immunization in rabbits

Immunization of New Zealand white rabbits with type V collagen in Freund adjuvant results in scleroderma-like skin changes. Over a period of 3 months, diffuse cutaneous fibrosis and mild interstitial lung disease develop in the rabbits, as well as changes in the pulmonary microvasculature. Moreover, antinuclear and antitopoisomerase autoantibodies also develop. Although the role of type V collagen in SSc is not well understood, elevated type V collagen expression has been documented in the lesional dermis in patients with SSc and correlates with the extent of skin involvement.

Sclerodermatous chronic graft-versus-host disease

Transplantation of bone marrow or spleen cells from a donor mouse (commonly the B10.D2 strain) into irradiated recipient mice (Balb/c) that differ at minor histocompatibility loci results in sclerodermatous GVHD. Dermal fibrosis develops 14 to 21 days after transplantation. In the early stage, skin infiltration with donor T cells and monocytes/macrophages is prominent. DNA microarray analysis of the skin showed overexpression of both Th1 and Th2 cytokines, TGF- β , and monocyte chemoattractant protein-1 (MCP-1). Induction of inflammation and fibrosis requires donor CD4+ naive T cells and either CD80/86-expressing donor or host antigen-presenting cells.

PATHOGENESIS

Overview of immunity, vascular injury, and fibrosis

The pathogenesis of SSc involves a unique triad of vascular damage, innate and adaptive autoimmunity, and generalized fibrosis. Even though each of these pathomechanistic processes contributes to disease burden, their individual importance varies from one patient to another, with some manifesting primarily vascular complications and others suffering predominantly fibrotic complications. This clinical heterogeneity and diverse outcomes of SSc are likely to be a reflection of the variable contributions of the three pathomechanistic processes in individual patients. Figure 143.8 presents an overview of pathogenesis in which the dynamic interplay between the distinct processes that are responsible for initiating, amplifying, and sustaining tissue damage in SSc is illustrated.

Heritable animal models of scleroderma

Tight skin 1 mouse

The *Tsk1*^{+/+} mouse was described more than 40 years ago as a spontaneously occurring mutant. The skin in these mice is thickened, especially in the intercapsular region, and is firmly bound to the underlying muscle. Histologic examination shows marked fibrosis in the hypodermis but no changes in the dermis. There is no significant difference in dermal collagen content between *Tsk1*^{+/+} mice and age-matched wild-type controls and no evidence of active TGF- β signaling in the skin. In contrast, substantial changes are noted in the expression of genes coding for microfibrillar proteins and Wnt, bone morphogenetic protein (BMP), and CCN3 signaling. *Tsk1*^{+/+} mice have no vasculopathy, and emphysema-like changes develop rather than pulmonary fibrosis. The *Tsk* mutation is an in-frame duplication of exons 17 to 40 of the fibrillin-1 gene that gives rise to an abnormally large molecule.⁵ Other fibrillin-1 gene mutations are associated with the fibrillinopathies, a family of developmental disorders that includes stiff skin syndrome and Marfan syndrome. A Marfan-like skeletal phenotype was described in *Tsk1*^{+/+} mice.⁶ Fibrillin-1 is a connective tissue microfibril that regulates elastic fiber assembly, binds to latent TGF- β binding protein 1 (LTBP-1) and LTBP-4, and controls the bioactivity of TGF- β . Marfan syndrome and a transgenic model of Marfan syndrome in mice are both associated with perturbed TGF- β signaling, which—at least in the mouse—can be reversed by pharmacologic TGF- β antagonism with losartan.⁷

Tight skin 2 mice

Tsk2^{+/+} mice have an autosomal dominant mutation mapped to chromosome 1; however, neither the genetic locus nor the underlying molecular defect is currently known. By 2 weeks of age, *Tsk2*^{+/+} mice have significant skin fibrosis. In contrast to *Tsk1*^{+/+} mice, fibrosis is prominent in the dermis and is accompanied by elastic fiber deposition and loss of subcutaneous adipose tissue. *Tsk2*^{+/+} mice have circulating antinuclear antibody and anticentromere, anti-topoisomerase I, and anti-RNA polymerase II autoantibodies. A modest increase in the perivascular adventitial layer has been detected, but the hallmark obliterative vasculopathy of SSc is absent. In contrast to *Tsk1*^{+/+} mice and human SSc, no pulmonary pathology is seen in *Tsk2*^{+/+} mice. Although early reports described mononuclear cell infiltrates in the dermis, a recent study was unable to reproduce these findings.

Constitutive transforming growth factor- β receptor signaling

A transgenic mouse strain expressing a constitutively active mutant TGF- β type I receptor, T β R1(ca), represents an important advance in modeling SSc.⁸ Crossing a knock-in mouse harboring T β R1(ca) with a transgenic mouse carrying fibroblast-specific inducible Cre recombinase generates T β R1(ca) Cre-ER(T) mice which, on subcutaneous injection of tamoxifen, show constitutive T β R1 activity in fibroblasts but not other cell types. By 5 months of age, diffuse skin fibrosis, loss of subcutaneous fat deposits, and excessive collagen deposition in the walls of small pulmonary arteries develop in the transgenic mice.

Inducible animal models of scleroderma

Bleomycin-induced scleroderma

The most widely used mouse model of scleroderma involves repeated subcutaneous injection of the chemotherapeutic agent bleomycin. Dermal sclerosis accompanied by epidermal hypertrophy and atrophy of subcutaneous adipose tissue develops in these mice. Although skin induration is confined to the injected area, fibrotic changes and increased collagen deposition also occur in the lungs and kidneys. Dermal fibrosis at 3 weeks is associated with myofibroblast accumulation and deposition of collagens, fibronectin, osteopontin and hyaluronic acid (Fig. e143.3). Lesional tissues show evidence of active TGF- β , CTGF, and Wnt signaling and elevated expression of the early

Fig. e143.3 Murine model of scleroderma: bleomycin-induced skin fibrosis. Subcutaneous injections of bleomycin induces dermal fibrosis. Note the hyperproliferative changes in the epidermis, thick and sclerotic dermis with obliteration of dermal adnexal structures, and loss of the subcutaneous adipose layer (upper panel, phosphate-buffered saline; lower panel, bleomycin; hematoxylin-eosin).

response gene *Egr-1*. Reactive oxygen species (ROSs) play a role in triggering inflammation and skin fibrosis, and subcutaneous injection of HOCl, which generates copious amounts of ROSs, mimics the fibrotic response elicited by bleomycin. Bleomycin-induced fibrosis was significantly attenuated in mice with deleted Smad3, β -catenin, or *Egr-1* and in transgenic mice overexpressing the Wnt antagonist Dickkopf-1, thus highlighting the important roles of TGF- β and Wnt signaling in pathogenesis.

Bleomycin-induced tissue fibrosis is mediated via a type 2 immune response, and more severe fibrosis develops in mice with targeted deletion of the type 1 transcription factor T-bet. Although a recent report suggested that CD4⁺ T cells can transfer disease in bleomycin-injected mice, dermal fibrosis can be induced in immunodeficient nude and Rag2^{-/-} mice. These results indicate that T cells are not required for the development of fibrosis by bleomycin.

Intratracheal administration of bleomycin is widely used to model lung fibrosis in rodents. The pulmonary lesions develop rapidly and show a predominantly bronchiolocentric distribution pattern similar to UIP, although the relevance of this model for interstitial lung disease has been questioned. Type 2 helper T-cell (Th2) skewing of the immune response is regulated by the transcription factor GATA3. An exaggerated form of lung fibrosis with increased TGF- β but decreased levels of interferon- γ (IFN- γ) develops in mice transgenic for GATA3 after bleomycin treatment. In mice overexpressing the Th2 cytokine interleukin-13 (IL-13), pulmonary fibrosis mediated via activation of TGF- β *in vivo* develops.

TABLE 143.2
Selected mouse models of scleroderma

Model*	Aspects of the pathogenesis of systemic sclerosis				Key features
	Vasculopathy, vascular activation	Inflammation	Autoimmunity	Fibrosis	
Naturally occurring					
Tsk1	–	–	+	+	Duplication mutation in the fibrillin-1 gene
Tsk2	–	+	+	+	Unknown genetic defect; early cutaneous inflammatory cell infiltrate
Induced					
Bleomycin (subcutaneous)	+	+	+	+	Production of reactive oxygen species, monocytic inflammation, TGF-β activation, topo I-specific autoimmunity. Progressive fibrosis in the skin; the lung and kidneys also affected
Topoisomerase I immunization	–	+	+	+	Freund complete adjuvant required for the phenotype
Angiotensin II	+	+	-	+	Fibrosis develops in skin and multiple organs
Collagen V immunization (rabbit)	+	+	+	+	Rabbits develop antibodies to type V collagen
GVHD (B10.D2 vs. Balb/c)	+	+	–	+	Transfer of spleen cells from B10.D2 mice into irradiated Balb/c mice results in chronic GVHD and fibrosis
GVHD (B10.D2 vs. Rag-2–/–)	+	+	+	+	Transfer of spleen cells into Rag-2-null mice results in systemic fibrosis, inflammation, autoantibodies
Transgenic					
Fibroblast-specific constitutively active TβRI	+	+	–	+	Expression of constitutively active mutant type I TGF-β receptor in fibroblasts causes tissue fibrosis
Wnt10b expression in adipocytes	–	–	–	+	Prominent dermal fibrosis and disappearance of intradermal adipose tissue
*All animal models use mice, except for the type V collagen immunization model, which uses rabbits. GVHD, graft-versus-host disease; TGF-β, transforming growth factor-β; TβRI, TGF-β receptor type I.					

*All animal models use mice, except for the type V collagen immunization model, which uses rabbits. GVHD, graft-versus-host disease; TGF- β , transforming growth factor- β ; T β RI, TGF- β receptor type I.

Fibrosis

Fibrosis is due to deregulated synthesis of and intermolecular interactions among collagens and other ECM macromolecules. Progressive buildup of biochemically and mechanically abnormal connective tissue disrupts tissue architecture and function, which accounts for much of the morbidity and mortality associated with SSc.

In skin fibrosis, a hallmark of SSc, the relative proportions of the main fibrillar collagens (types I and III) are comparable to those in healthy skin. In contrast, the nonfibrillar type VII collagen, which is normally restricted to the basement membrane, is abundant throughout the lesional dermis. Fibronectin is a 220-kDa modular matrix protein with important functions in fibroblast attachment, spreading, and locomotion. An alternately spliced variant of fibronectin that includes the extra domain A (fibronectin-EDA [Fn-EDA]) is required for myofibroblast differentiation and functions as both a structural protein and a signaling molecule. In addition, levels of type V and type VI collagen, hyaluronic acid, COMP (an 86-kDa glycoprotein that regulates collagen fibrillogenesis), lysyl oxidase, and lysyl hydroxylase (PLOD2, an enzyme that catalyzes extracellular collagen cross-linking) are elevated. Recent studies of SSc using DNA microarray technology have revealed strikingly altered patterns of gene expression in the skin (see Fig. e143.1). Many genes that encode collagens and other ECM components (SPARC and COMP) or signaling molecules (TGF- β , CTGF [CCN2], and Wnt) are elevated in comparison to healthy skin. Overexpression of COMP, a protein normally found in cartilage and tendons but not in skin, was also confirmed by immunohistochemistry. Moreover, serum levels of COMP correlate with both the clinical skin score and survival. Because COMP catalyzes collagen fibrillogenesis and enhances cell survival, its upregulation in SSc may be important in the development of fibrosis. The number of genes differentially expressed between normal and SSc biopsy specimens is much greater in skin samples than in explanted dermal fibroblasts, thus indicating time-dependent “extinction” of the activated gene expression in fibroblast cultures. Remarkably, microarray studies have consistently shown that the gene expression profile in SSc fails to distinguish clinically involved and uninvolved skin.

Pathogenesis of fibrosis: cellular and molecular determinants

Fibrosis is characterized by replacement of normal tissue architecture with compact, mechanically stressed, rigid connective tissue. The normal ECM

is composed of the cellular compartment, with both resident cells and circulation-derived infiltrating cells, and acellular connective tissue, which consists of fibrillar and nonfibrillar collagens, fibronectin, SPARC, proteoglycans, elastins, fibrillins, COMP, and adhesion molecules.¹⁰ A major function of the ECM is sequestration of growth factors (e.g., TGF- β) and matricellular proteins (e.g., CCN2/CTGF) in a biologically latent form. The excessive accumulation of connective tissue results from overproduction by activated mesenchymal cells that are responding to soluble molecules, the surrounding ECM, hypoxia, cell-cell interactions, or mechanical cues. Impaired connective tissue turnover and expansion of the biosynthetically activated fibroblast pool further exacerbate the pathologic fibrogenesis.

Cellular determinants of fibrosis

Fibroblasts

Fibroblasts are versatile tissue-resident mesenchymal cells. Fibroblasts derived from different anatomic sites display highly divergent patterns of gene expression that are faithfully retained over time. This “positional memory” is maintained by the distribution of Hox genes called the Hox code.¹¹ In response to extracellular signals, resident fibroblasts or their progenitor cells are induced to migrate and proliferate; produce collagens and other connective tissue molecules; adhere to, contract, and remodel the ECM; secrete growth factors, cytokines, and chemokines; express surface receptors; and differentiate into apoptosis-resistant myofibroblasts. In contrast to the physiologic response to tissue injury in which the fibroblast repair program is tightly controlled and self-limited, pathologic fibrosis is characterized by unopposed fibroblast activation.

Myofibroblasts

The pool of biosynthetically activated effector cells responsible for pathologic matrix accumulation in lesional tissues is expanded through transdifferentiation of differentiated resident cells and influx of circulation-derived mesenchymal progenitor cells.¹² Myofibroblasts are α -smooth muscle actin-positive specialized cells that arise from resident mesenchymal cells in response to TGF- β and Fn-EDA.¹³ Their primary physiologic role is contraction of early granulation tissue during wound healing, where myofibroblasts are detected transiently and then disappear via apoptosis. In contrast, pathologic fibrogenesis is characterized by the persistence of myofibroblasts in lesional tissue, which results in an excessively contracted chronic scar.¹⁴ Myofibroblast contraction itself leads to activation of latent TGF- β , liberation of it from the matrix, and further stimulation of myofibroblast

OVERVIEW OF SYSTEMIC SCLEROSIS PATHOGENESIS: INTEGRATING VASCULAR, IMMUNE, AND FIBROTIC PROCESSES

Fig. 143.8 Injury to vascular endothelium initiates a sequence of events, including the release of proinflammatory mediators, growth factors, chemokines, and reactive oxygen species (ROSs), that activate repair processes and lead to widespread tissue injury. Transition from innate immunity (macrophages) to the adaptive immune responses is accompanied by T-cell activation and the development of a type 2 immune response. Type 2 helper T-cell (Th2) cytokines such as interleukin-4 (IL-4), IL-5, and IL-13 exhibit profibrotic activity and orchestrate tissue repair. Regulatory T cells (Tregs) produce transforming growth factor- β (TGF- β). B-cell stimulation leads to the generation of specific autoantibodies that may directly contribute to tissue damage. Failure to replace damaged endothelium from circulating endothelial progenitors enhances leukocyte emigration. Chronic injury leads to persistent fibroblast activation, increased matrix accumulation, and tissue rigidity. CEP, circulating endothelial precursor; MMP, matrix metalloproteinase; TNF, tumor necrosis factor. (Modified from Abraham DJ, Varga J. Scleroderma: from cell and molecular mechanisms to disease models. *Trends Immunol* 2005;26:587-95.)

activation in a self-amplifying vicious cycle. In SSc, the extent of myofibroblast accumulation in the dermis correlates with the extent of skin involvement.¹⁵

Pericytes

Pericytes are contractile cells of mesenchymal origin that normally reside in the walls of microvessels, where they form intimate contact with the underlying endothelium. They can be identified by the surface markers CD248 and PDGFR β . Pericytes play an important role in integrity of the microvasculature. Injured pericytes detaching from endothelial cells migrate into the interstitium, where in response to PDGF they differentiate into collagen-producing myofibroblasts. Moreover, detachment of perivascular pericytes from the vessel wall results in loss of pericyte coverage of endothelial cells, which leaves an unstable endothelium prone to rarefaction and thereby links microvascular injury and fibrosis.

Cellular plasticity in systemic sclerosis

During embryonic development and under certain conditions in adults, fully differentiated epithelial cells transform into fibroblasts through the process of epithelial-mesenchymal transition (EMT). During EMT, epithelial

cells lose cell-cell adhesion and apical polarity and acquire mesenchymal features such as motility, invasiveness, heightened resistance to apoptosis, and synthesis of ECM molecules. In cultured cells, EMT can readily be induced by hypoxia, ROSs, Wnts, and TGF- β and is reversed by BMP-7, a member of the TGF- β superfamily. The importance of EMT in the pathogenesis of fibrosis and its role in SSc remain controversial. Recent studies suggest that adipocytic mesenchymal progenitor cells also differentiate into myofibroblasts. In addition, microvascular adventitial pericytes transition to myofibroblasts in response to injury and play a role in SSc and other forms of fibrosis.

Cellular determinants of fibrosis: bone marrow-derived mesenchymal progenitor cells

Bone marrow-derived progenitor cells called fibrocytes have also been implicated in SSc. Fibrocytes are CD34+ progenitor cells normally present in small numbers in peripheral blood that have the unique ability to both synthesize collagen and present antigen. Fibrocytes are identified by expression of CD14+ and the chemokine receptors CCR3, CCR5, and CXCR4. Monocyte-derived circulating multipotent progenitor cells can also differentiate into fibrocytes. This process is modulated by serum amyloid protein

TABLE 143.3
Soluble mediators implicated in fibrosis in systemic sclerosis

Growth factor	Cellular source	Elevated in systemic sclerosis
TGF-β	Inflammatory cells, platelets, fibroblasts, macrophages	+
PDGF	Platelets, macrophages, fibroblasts, endothelial cells	+
CTGF/CCN2	Fibroblasts	+
Insulin-like growth factor-1	Fibroblasts	+
IL-4 and IL-13	Th2 lymphocytes, mast cells	+
IL-6	Macrophages, B cells, T cells, fibroblasts	+
Chemokines (MCP-1, MCP-3)	Neutrophils, epithelial cells, endothelial cells, fibroblasts	+
CXCL4	pDCs	++
Fibroblast growth factor	Fibroblasts	+
Endothelin-1	Endothelial cells	+

CTGF, connective tissue growth factor; IL-4, interleukin-4; MCP, monocyte chemoattractant protein; pDC, plasmacytoid dendritic cell; PDGF, platelet-derived growth factor; TGF-β, transforming growth factor-β; Th2, type 2 helper T cell.

A (SAP), a serum pentraxin closely related to C-reactive protein. Impaired SAP production or deregulated SAP signaling might be implicated in fibrosis and SSc.

Molecular determinants of fibrosis

During physiologic tissue remodeling, synthesis of collagen is tightly regulated. In addition to TGF-β, multiple soluble molecules modulate collagen synthesis through autocrine and paracrine signaling (Table 143.3). Cell-cell contact, integrin-mediated contact with the surrounding ECM, hypoxia, and biomechanical forces also exert profound effects on myofibroblast accumulation and collagen production.¹⁶ The collagen genes harbor conserved regulatory elements that are specifically recognized by positively acting transcription factors such as Sp1, Ets1, Smad3, Egr-1, and CCAAT-binding factor (CBF), whereas Sp3, C/EBP, YB1, c-Krox, and Fli-1 inhibit collagen gene expression. Transcription factors interact in complex signaling networks and recruit coactivators and corepressors, scaffold proteins, and chromatin-modifying enzymes such as p300/CBP, and histone deacetylases (HDACs) that modulate transcription via chromatin modifications.¹⁷

Cell-autonomous regulation of collagen synthesis

Multiple biologic mechanisms exist for suppressing fibrogenic responses and preventing excessive scarring. Smad7, which blocks TGF-β signaling and fibrotic responses, has been shown to be defective in SSc. Other cell-autonomous repressors of fibrosis include transcription factors (Fli-1, p53), the Egr-1 antagonist Nab2, the nuclear orphan receptor peroxisome proliferator-activated receptor-γ (PPAR-γ), phosphatase and tensin homologue deleted on chromosome 10 (PTEN), HDACs, DDR2, and microRNA such as miR-29 (Box 143.2). These intrinsic molecules normally function as natural breaks that restrain collagen synthesis. Impaired expression, regulation, or function of these molecules contributes to fibrosis.

Transforming growth factor-β is a master regulator of connective tissue remodeling

The multifunctional cytokine TGF-β induces a broad array of fibrotic responses (see Box 143.2) and plays a fundamental and dominant role in both physiologic fibrogenesis (wound healing and tissue repair) and pathologic fibrosis.¹⁸ In most cell types, TGF-β is secreted as an inactive precursor complexed to latent TGF-β binding protein (LTBP) and is sequestered within the ECM. On tissue injury, latent TGF-β is converted to its biologically active form. Activation of latent TGF-β is catalyzed by thrombospondins and plasmin or via cell-surface integrins (α_vβ₃, α_vβ₅, α_vβ₆, and α_vβ₈) and is further enhanced by increasing matrix stiffness.

Intracellular TGF-β signaling involves both canonic Smad and Smad-independent signaling cascades. Canonic TGF-β signal transduction involves sequential phosphorylation of the type I TGF-β receptor activin-like kinase 5 (ALK5), a serine-threonine kinase, followed by activation of cytoplasmic

BOX 143.2 FIBROGENIC ACTIVITIES OF TRANSFORMING GROWTH FACTOR-β THAT MAY HAVE A ROLE IN SYSTEMIC SCLEROSIS

- Stimulates the synthesis of extracellular matrix (fibrillar collagens, fibronectin, proteoglycans, elastin, tissue inhibitors of metalloproteinases)
- Inhibits matrix metalloproteinases
- Stimulates fibroblast proliferation, adhesion, chemotaxis
- Stimulates cartilage oligomeric protein and PLOD2 production
- Enhances collagen fibrillogenesis and cross-linking
- Enhances stiffness of the extracellular matrix
- Stimulates connective tissue growth factor and endothelin-1 production
- Stimulates the production of reactive oxygen species
- Stimulates the expression of surface receptors for transforming growth factor-β and platelet-derived growth factor
- Promotes fibroblast-myofibroblast and monocyte-fibrocyte differentiation
- Induces epithelial-mesenchymal and endothelial-mesenchymal transitions
- Inhibits fibroblast apoptosis

Smads (Fig. e143.4a). The activated Smad complex binds to conserved DNA sequences in target gene promoters and recruits transcriptional cofactors such as the histone acetylase p300/CBP. Pharmacologic blockade of ALK5 activity prevents collagen accumulation and myofibroblast differentiation.

Smad-independent transforming growth factor-β signaling

Recent evidence indicates the existence of non-Smad pathways mediating TGF-β responses. As shown in Figure e143.4b, non-Smad signal transduction involves the mitogen-activated protein kinase ERK1/2 and its target Egr-1, other protein kinases (p38 and JNK, focal adhesion kinase [FAK], and TGF-β-activated kinase [TAK1]), lipid kinases such as phosphatidylinositol 3'-kinase and its downstream target (Akt), and the non-receptor tyrosine kinase c-Abl.

The Egr-1 transcription factor belongs to a family of inducible immediate-response genes that also includes Egr-2, Egr-3, Egr-4, and their repressors Nab1 and Nab2. Expression of Egr-1 is induced rapidly and transiently by hypoxia, injury, ROSs, and TGF-β. Egr-1 stimulates collagen gene expression and myofibroblast differentiation and enhances TGF-β synthesis, as well as TGF-β receptor expression. Egr-1 expression is constitutively upregulated in SSc. Mice with targeted deletion of Egr-1 have attenuated fibrotic responses to bleomycin. Nab2 is an inducible corepressor of Egr-1 signaling that inhibits Egr-1-mediated fibrotic responses in a negative feedback loop.

c-Abl is a non-receptor tyrosine kinase that regulates cell proliferation and survival, and its chromosomal translocation (Bcr-Abl) underlies chronic myelogenous leukemia. The c-Abl pathway is constitutively activated in patients with SSc. The tyrosine kinase inhibitor imatinib mesylate (Gleevec) blocks c-Abl-mediated Egr-1 activation and stimulation of collagen gene expression and myofibroblast differentiation *in vitro* and ameliorates bleomycin-induced skin fibrosis in mice.¹⁹

Peroxisome proliferator-activated-γ: the interface between adipogenesis and fibrosis

PPAR-γ is the master regulator of adipogenesis. Recent studies have linked PPAR-γ with inflammation, atherosclerosis, cancer, and fibrosis. Ligands of PPAR-γ abrogate profibrotic TGF-β responses and block the stimulation of Egr-1. The antifibrotic effects are mediated in part through endogenous adipokines such as adiponectin, a member of the complement 1Q-TNF related protein (CTRP) family. Expression of PPAR-γ is upregulated during the resolution phase of wound healing. Treatment of normal mice with rosiglitazone, a potent synthetic PPAR-γ agonist, attenuates bleomycin-induced scleroderma. In contrast, fibroblast-specific deletion of PPAR-γ results in exaggerated skin fibrosis. PPAR-γ mRNA expression and activity are markedly impaired in SSc skin and lung biopsy specimens and in explanted fibroblasts. Because PPAR-γ is a requisite factor for normal adipogenesis, impaired PPAR-γ may account for the prominent loss of hypodermal adipose tissue in SSc.²⁰

Integrin signaling in systemic sclerosis

Fibroblast activity is modulated by the pericellular matrix via cell-surface integrin receptors. Expression of α_vβ₃ and α_vβ₅ integrins is significantly elevated in SSc fibroblasts. These integrins contribute to elevated collagen synthesis and myofibroblast differentiation by activating latent TGF-β and inducing a self-amplifying autocrine feedback loop.

Fig. e143.4 Intracellular transforming growth factor- β (TGF- β) signaling via canonic and noncanonic pathways. TGF- β binds to and activates cell-surface receptors, which results in the phosphorylation of intracellular downstream targets. Activated Smad2 and Smad3 form a complex with Smad4 and transit from the cytoplasm into the nucleus, bind to DNA, and activate (or repress) target gene transcription (a). TGF- β can also activate complex Smad-independent intracellular kinase cascades (b). ECM, extracellular matrix; SBE, Smad binding element.

Biomechanical signaling

Mechanical forces are important modulators of fibroblast morphology, migration, and proliferation; matrix synthesis; and myofibroblast differentiation.¹⁴ As the skin and other tissues become fibrotic, they show increased stiffness and reduced elasticity, which results in mechanical stress. In turn, resident fibroblasts sense biomechanical forces through integrins and changes in cytoskeletal tension mediated by Rho-associated kinase and FAK, which play critical roles in driving persistent fibrogenesis. Activation of these pathways by the stiff matrix perpetuates fibroblast activation and further exacerbates the fibrosis. Moreover, fibroblasts within a stiff matrix can activate latent TGF- β sequestered within the pericellular environment. Remarkably, fibroblasts that are activated as a result of increased substrate stiffness maintain their activated phenotype even when placed in a soft substrate. The phenomenon of “fibroblast mechanical memory,” apparently driven by stable epigenetic modifications, indicates that exposure to biomechanical forces can permanently alter fibroblast function and promote a sustained fibrotic phenotype.²¹ In this manner, a stiff matrix resulting from fibrosis of affected tissue itself drives fibroblast activation, thereby contributing to a self-amplifying loop of sustained fibrogenesis.

Fibrogenic growth factors and chemokines

Multiple growth factors, chemokines and eicosanoids, adenosine, and ROSs that regulate fibroblast biology are abnormally expressed in SSc. These molecules represent potential targets for antifibrotic therapy (see Table 143.3).

Connective tissue growth factor/CCN2

CTGF/CCN2 is a cysteine-rich, 40-kDa matricellular protein with important roles in angiogenesis, wound healing, and development. CTGF/CCN2 expression is generally undetectable in normal tissue but is markedly elevated in SSc, and serum levels correlate with the extent of skin and pulmonary fibrosis in SSc. CTGF/CCN2 expression is induced by TGF- β , IL-4, and vascular endothelial growth factor (VEGF), whereas tumor necrosis factor- α (TNF- α) and iloprost block stimulation. Injection of CTGF/CCN2 by itself induces only a transient fibrotic response in mice but markedly enhances the TGF- β response. Because the biologic responses to CTGF/CCN2 mirror those induced by TGF- β , it has been proposed that the effects of TGF- β are mediated through endogenous CTGF/CCN2; however, CCN2-null fibroblasts show intact TGF- β signaling.

Platelet-derived growth factor

PDGFs are disulfide-linked heterodimeric peptides consisting of an A and a B chain that act mainly on stromal cells such as fibroblasts, smooth muscle cells, and pericytes. The PDGFs play a vital role in wound healing and are increasingly being implicated in fibrosis. Originally isolated from platelets, PDGF isoforms are also secreted by monocytes and macrophages, endothelial cells, and fibroblasts. Since PDGFs play important roles in regulating the differentiation, proliferation, and survival of mesenchymal progenitor cells, dysregulated PDGF signaling plays a role in fibrosis. Signaling via the PDGFR α and PDGFR β receptors, PDGFs act as potent mitogens and chemoattractants and induce collagen, fibronectin, and proteoglycan synthesis; TGF- β secretion; and pericyte differentiation into myofibroblasts. An alternative mechanism for activation of PDGFR signaling by circulating autoantibodies binding to PDGFRs has recently been proposed. Severe multiple-organ fibrosis develops in transgenic mice that overexpress either PDGF isoforms or mutated constitutively active PDGFR α . Expression of PDGF and its receptors is elevated in SSc skin and bronchoalveolar lavage fluid. Although some reports have described the presence of activating autoantibodies to the PDGF receptor in the serum of patients with SSc,²² subsequent reports failed to reproduce these findings.

Wnt/ β -catenin signaling

Microarray studies provide evidence of deregulated Wnt signaling in SSc and in mouse models of scleroderma. The Wnt family of morphogens comprise multiple secreted glycoproteins that regulate development and embryogenesis. Extensive crosstalk between Wnts and the TGF- β and BMP signaling pathways exists; Wnts stimulate TGF- β , and TGF- β can activate β -catenin. The Wnt/ β -catenin pathway can promote fibrogenesis through increased fibroblast proliferation and activation, as well as induction of EMT and other forms of cellular differentiation. Striking scleroderma-like skin induration develops in mice transgenic for Wnt10b.²³

Th2 cytokines in systemic sclerosis

Th2 cytokines stimulate fibroblast proliferation, chemotaxis, collagen synthesis, and production of TGF- β , CTGF/CCN2, and tissue inhibitor of

metalloproteinases (TIMPs). Serum levels of IL-4 and IL-4-producing T lymphocytes are elevated in patients with SSc. Expression of IL-4 is also elevated in lesional skin and cultured fibroblasts. IL-6, produced by T lymphocytes, fibroblasts, and endothelial cells, stimulates collagen and TIMP-1 synthesis and promotes a Th2-polarized immune response. Serum IL-6 levels are elevated in SSc and correlate with skin involvement. IL-13 has been implicated in asthma and fibrotic conditions. It has both indirect (stimulation of TGF- β production) and direct (stimulation of fibroblast proliferation and collagen synthesis) profibrotic effects. Serum levels of IL-13 are elevated in patients with SSc.

Chemokines in systemic sclerosis

Chemokines play important roles in angiogenesis, wound healing, and fibrosis. The CC chemokine MCP-1 stimulates collagen production directly, as well as through endogenous TGF- β . Serum levels of MCP-1, along with those of macrophage inflammatory protein-1 α (MIP-1 α), IL-8, CXCL8, and CCL18, are elevated in SSc and correlate with the severity of skin fibrosis. Mononuclear cells and fibroblasts from SSc patients produce these chemokines spontaneously, and lesional fibroblasts show constitutive upregulation of the MCP-1 receptor CCR2. MCP-1-null mice are resistant to induction of fibrosis. Strong expression of MCP-1 and MCP-3 was noted in lesional skin in SSc, particularly in early disease. Levels of MIP-1 α , CXCL8 and CCL18, RANTES (regulated on activation, T cell expressed and excreted), PARC, and the CXC chemokines IL-8, MIP-2, and fractalkine are also overexpressed in SSc or in animal models of scleroderma. The insulin-like growth factor (IGF) binding protein-1 (IGFBP-1) stimulates collagen synthesis and fibroblast proliferation and induces TGF- β . Patients with SSc have elevated levels of IGF-1 in bronchoalveolar lavage fluid. Expression of IGFBP-3 is markedly elevated in SSc fibroblasts.^{24,25} IGFBP-5 induces scleroderma-like fibrosis in mice.

Endogenous ligands for Toll-like receptors

Toll-like receptors (TLRs) are expressed on both leukocytes and parenchymal cells and serve as critical mediators of innate immunity. Recent evidence has implicated TLR4-mediated innate immune signaling in tissue fibrosis.²⁶ Matrix molecules and their fragments generated *in situ* during tissue damage, such as low-molecular-weight fragments of hyaluronan, biglycan, gp96, and Fn-EDA, are capable of inducing TLR activation. These so-called danger-associated molecular patterns (DAMPs) are aberrantly upregulated in lesional tissue in SSc patients and in mouse models of scleroderma. Stimulation of TLR4 in normal fibroblasts with neoligands such as Fn-EDA induces myofibroblast transdifferentiation, TGF- β secretion, and collagen production. Activation of fibroblast TLRs by DAMPs in SSc might account for the persistence of tissue fibrosis.

Adenosine

Adenosine is a purine nucleoside whose extracellular concentration is rapidly elevated in response to injury or IL-13. Adenosine is a potent stimulus for collagen synthesis via the A2A receptor and MEK1/ERK signal transduction in fibroblasts. Fibrosis is attenuated in mice with targeted deletion of the adenosine receptor.

Paracrine mediators with antifibrotic activity

Soluble mediators can also act as negative regulators of fibrotic responses. IFN- γ , a hallmark Th1 cytokine, inhibits collagen gene expression and abrogates TGF- β stimulation of fibroblast proliferation, matrix contraction, and myofibroblast differentiation. Fibroblasts from patients with SSc are relatively resistant to these inhibitory effects. Hepatocyte growth factor (HGF) is normally secreted by mesenchymal cells and regulates epithelial cell proliferation and function. *In vitro*, HGF inhibits collagen synthesis in normal and SSc fibroblasts. Adiponectin, secreted primarily by adipocytes, has pleiotropic protective effects. Levels of adiponectin are reduced in the serum and lesional tissues of SSc patients and show an inverse correlation with the extent of skin fibrosis. *In vitro*, adiponectin acts as a potent inhibitor of fibroblast activation via induction of adenosine monophosphate kinase. BMP-7, a member of the TGF- β superfamily, is a potent inhibitor of EMT that can prevent and ameliorate fibrosis in various animal models.

Tumor necrosis factor- α

The role of TNF- α in the pathogenesis of SSc is difficult to discern. In cultured fibroblasts, TNF- α acts as a potent inhibitor of collagen gene expression and blocks the fibrotic responses induced by TGF- β . Microarray analysis of sclerodermatous GVHD showed that relative absence of TNF- α in the lesional skin accounted for the development of skin fibrosis rather than epithelial cytotoxicity in this mouse model of scleroderma. Furthermore, mice with targeted deletion of the receptor for TNF- α show

accelerated fibrosis, and transgenic mice overexpressing TNF- α were partially protected from the lung fibrosis induced by bleomycin. In other studies, however, transgenic expression of TNF- α in the lungs was shown to induce pulmonary fibrosis.

The scleroderma fibroblast

Fibroblasts explanted from lesional skin and lung fibroblasts from patients with SSc variably display an abnormal activated phenotype that is partially maintained during their serial passage *in vitro*.²⁷ The “SSc phenotype” is characterized by constitutively increased collagen gene expression and enhanced ECM synthesis, secretion of profibrotic cytokines and chemokines, spontaneous production of ROSs, and increased expression of cell-surface receptors for TGF- β and PDGF. Lesional SSc fibroblasts in culture display a myofibroblast phenotype with activation of FAK.²⁸ It remains unsettled whether the activated SSc fibroblast phenotype represents a stable and heritable abnormality inherent in these cells (possibly because of stable epigenetic histone chromatin modifications) or instead reflects exogenous stimulus-induced activation.

The signal transducers, cofactors, and transcriptional regulatory molecules that are aberrantly regulated in SSc fibroblasts are shown in Box 143.3. Because the characteristic SSc fibroblast phenotype can be induced by TGF- β treatment of explanted normal fibroblasts, it has been suggested that the SSc fibroblast phenotype is due to persistent autocrine TGF- β signaling.²⁹ Moreover, SSc fibroblasts have elevated levels of TGF- β receptors and overexpress thrombospondin and integrins, which can locally activate latent TGF- β at the cell surface. Consistent with the autocrine TGF- β hypothesis, SSc fibroblasts show constitutive TGF- β signaling along with nuclear accumulation of activated Smad3 and constitutive Smad3 interaction with the histone acetyltransferase coactivator p300/CBP. Other studies have demonstrated defective expression or function of endogenous suppressors of TGF- β signaling such as Smad7, PPAR- γ , and caveolin-1, thus suggesting

that failure to shut off activation pathways represents a fundamental intrinsic cell defect in SSc fibroblasts.

Inflammation and immunity

The immune response in systemic sclerosis

As we consider pathogenic mechanisms, we quickly come to conflicting viewpoints and understanding of the role of immunity and autoimmunity in scleroderma. Advocates of the importance of immunity in SSc find support in the nearly universal presence of circulating autoantibodies and of mononuclear cells in affected organs. Skeptics argue that autoantibodies and inflammatory cells are not clearly implicated in directly (or indirectly) causing any pathogenic features of the disease. Despite these reservations, immune dysregulation is apparent at multiple levels in SSc patients and may well be the primary trigger of the disease (Fig. 143.9).

Humoral immunity in pathogenesis

Autoantibodies in SSc might play two different roles: directly mediate tissue injury or alternatively regulate the immune response.

Autoantibodies implicated in tissue damage in systemic sclerosis

Multiple autoantibodies occur in SSc that might directly mediate tissue damage. A list of potentially pathogenic autoantibodies is presented in Table 143.4. Anti-endothelial cell antibodies (AECAs) have been described in SSc that could effectively link autoimmunity and vascular injury. Several investigators have reported cytotoxicity and apoptosis mediated by AECAs. Despite these observations, the importance of AECAs in SSc remains uncertain because different assays are used, their titers are not consistently higher in SSc than in patients with other connective tissue disease, and they appear to lack specificity for endothelial cells. In patients with diffuse cutaneous SSc, AECAs were found to target topoisomerase I, and in patients with limited cutaneous SSc, AECAs were found to target CENP-B, the main target of anticentromere antibodies.

Antibodies to fibroblasts might play a direct role in the pathogenesis of fibrosis. Recent findings include identification of topoisomerase I as a target of antifibroblast antibodies, stimulatory antibodies to the PDGF receptor,³⁰ and upregulation of TGF- β expression by antibodies to fibrillin-1 *in vitro*.^{31,32} However, other studies have failed to confirm these observations.

Nuclear autoantibodies in systemic sclerosis

Another group of SSc-associated autoantibodies react against nuclear components. The list includes antibodies targeting anti-topoisomerase I (also known as Scl-70), centromere proteins (most consistently CENP-B), RNA polymerases I and III, and nucleolar proteins such as U3 and fibrillarin. These antibodies have strong associations with specific disease subsets and organ manifestations, and the stimulus for their production might provide important clues to the pathogenesis of SSc.

Fig. 143.9 Multiple cell types may be involved in stimulating vascular injury and fibrosis. Ligands for Toll-like receptors (TLRs) stimulate dendritic cells to produce interferon- α (IFN- α) and interleukin-6 (IL-6), which in turn stimulate B cells and monocytes/macrophages. Type 2 helper T cells (Th2 TCs) produce IL-4 and IL-13 and stimulate profibrotic “alternatively activated/M2” monocyte/macrophages. Macrophages produce profibrotic cytokines such as transforming growth factor- β (TGF- β) and platelet-derived growth factor (PDGF). Cytotoxic T cells may injure endothelial cells through granzyme and Fas/FasL. The resulting apoptotic cell debris may be sources for altered antigens that contribute to activation of B cells for production of autoantibodies. Autoantibody/autoantigen/nucleic acid complexes may also be internalized by B cells and dendritic cells activating TLRs.

TABLE 143.4
Pathogenetic autoantibodies in systemic sclerosis

Antibody	Target antigen/biologic response
Antiendothelial cell	Endothelial cells
Antifibroblast	Fibroblast cell membrane
Anticollagenase	MMP-1
Anti-PDGF receptor	Cell-surface receptor for PDGF
Anti-topoisomerase I	Induces scleroderma in immunized mice
Anti-angiotensin II receptor 1	Stimulates fibroblast activation
Anti-endothelin 1	Fibroblast activation
Anti-fibrillin-1	Extracellular microfibrils

MMP-1, matrix metalloproteinase-1; PDGF, platelet-derived growth factor.

Neoantigens as autoimmune targets

It has been suggested nuclear autoantigens become targets in SSc because of exposure of “neoepitopes,” that is, antigenic structures not previously seen by the immune system. One intriguing observation is that hypoxia in the presence of certain metals stimulates fragmentation of the autoantigens targeted in SSc.³³ Other insight into the role of SSc-associated autoantibodies comes from mouse strains in which mercury exposure elicits autoantibodies to fibrillar, an antigen targeted by antinucleolar antibodies in some patients with SSc. The protein fragments generated during mercury-induced cell death might be the cause of mercury-induced autoantibodies. ROSs can cause oxidation of autoantigens leading to immune responses to SSc-targeted autoantigens such as topoisomerase I and centromere proteins. These studies suggest a paradigm whereby proteolysis and other modification of autoantigens, caused by somatic mutations, hypoxia, mercury, cell death, or oxidation, trigger the generation of SSc-associated autoantibodies by creating neoepitopes. Whether modified antigens are responsible for the development of SSc-associated autoantibodies in patients with SSc is unknown.

Autoantibodies to nuclear autoantigens in innate responses

Although a direct role in pathogenesis has not been assigned to SSc-associated nuclear autoantibodies, recent data have suggested possible roles in innate immunity. Nucleic acid-containing immune complexes in SLE can stimulate innate immune responses through intracellular nucleic acid receptors that normally respond to microbial DNA or RNA. These include TLR3, TLR7, or TLR9, which bind respectively to double-stranded RNA, single-stranded RNA, and DNA. Several observations suggest innate immune activation in SSc (see later), and direct evidence of TLR responses has been reported primarily in sera containing anti-topoisomerase I. Although topoisomerase I is a DNA-nicking enzyme, it also associates with a variety of proteins that bind RNA. Thus, topoisomerase I in immune complexes in SSc sera might bind DNA or RNA. Internalization of these nucleic acid-containing complexes by dendritic cells appears to stimulate nucleic acid-sensing TLRs as assessed by IFN- α production. Treatment of antitopoisomerase-containing sera from SSc patients with RNase inhibits IFN- α secretion. Thus, TLR7, a single-stranded RNA sensor, is most strongly implicated in stimulation of innate immune responses by antitopoisomerase-containing immune complexes.

Cellular immunity in systemic sclerosis

A major branch point in considering immune pathogenesis is the role of innate versus adaptive immunity. Posed differently, the question is whether the immune process is being driven by responses to specific antigenic stimuli or more general immune stimuli. Although these two arms of the immune system are closely integrated, it is useful to consider evidence for the role of each. At the outset, the defined specificities of autoantibodies found in SSc suggest “adaptive” or antigen-specific immune responses. However, it is important to consider that these specificities might instead be driven by TLR-mediated “innate” immune responses designed to recognize pathogen-associated molecular patterns (PAMPs). Innate immune stimuli might serve to simply amplify antigen recognition caused, for example, by the modified neoantigens discussed earlier.

Innate immunity and dendritic cells in systemic sclerosis

Several recent observations have suggested that the innate immune system is activated in SSc. Increased expression of IFN-responsive genes, known as the IFN “signature” and initially identified in SLE, was found in SSc. Type

I IFNs are secreted upon TLR activation in dendritic cells, which are prominent in SSc lesional skin. The IFN signature is interpreted as evidence of dendritic cell activation. In SSc, TLRs could become activated through the same mechanisms as in SLE, that is, by nucleic acid-containing immune complexes or through the other endogenous ligands discussed earlier. Although type I IFNs have been implicated in the pathogenic aspects of lupus, they have not generally been considered pathogenic factors in SSc because they block the effects of TGF- β on fibrosis. Dendritic cell activation also stimulates TNF and IL-6 production, and these or other undefined mediators might further contribute to pathogenesis in SSc.

Toll-like receptor activation and autoreactive B cells

TLR activation is also a key step in autoreactive B-cell maturation. Notably, TLR7 has been implicated in the formation of antinucleolar antibodies in mice harboring the Y-linked autoimmune accelerator (*Yaa*) gene, which is associated with a duplication of TLR7. These results suggest that autoreactive B cells specific for nucleolar antigens can be activated to secrete autoantibody by taking up nucleolar/RNA-containing cellular debris through surface immunoglobulin receptors. Internalized nucleolar/RNA can bind TLR7 and thereby activate B-cell maturation. Similar mechanisms might lead to autoantibodies to other nucleic acid-binding proteins in SSc, such as anticentromere, antitopoisomerase, and anti-Th/To.

Th2 immune skewing, interleukin-13, and fibrosis

Clinical observations in both SSc and mouse models of fibrosis as discussed earlier implicate Th2 mediators in pulmonary fibrosis. Most importantly, IL-13, a signature Th2 cytokine, stimulates fibrosis in bleomycin-induced murine models of skin and pulmonary fibrosis.³⁴ IL-4 and IL-13 are elevated in the sera of SSc patients, thus suggesting that they play a role in the fibrotic disease in SSc. The results from a recent study showing that circulating T cells from SSc patients are skewed toward a Th2 phenotype and are associated with interstitial lung disease are consistent with these observations. In contrast, patients with SSc and PAH tended to have Th1-skewed T cells for reasons not yet understood.

A genome-wide microarray expression profiling study compared the mouse model of chronic GVHD with SSc skin. The results showed that the IL-13 target MCP-1/CCL2 is overexpressed in both the cGVH mouse model and SSc.³⁵ The fibrotic process was ameliorated in MCP-1/CCL2-null mice.

Monocyte/macrophage activation in fibrosis

Macrophages secrete a variety of profibrotic mediators, including PDGF and TGF- β . Dermal macrophages in SSc patients show activated phenotypes with increased expression of the type I IFN-inducible Siglec-1 and IFN- γ -inducible allograft inflammatory factor-1 (AIF1), a finding implicating IFNs in macrophage activation in SSc. However, since type I and type II IFNs stimulate similar genes, including Siglec-1 and AIF1, either type I or type II IFNs might be responsible for the increased expression of these genes in SSc. Because type I IFNs are typically secreted by activated dendritic cells whereas type II IFNs are typically secreted by natural killer and T cells, determining the type of IFN or IFNs upregulated in SSc might provide some additional hints about the nature of the underlying cellular immune response.

An emerging paradigm defines macrophage activation on the basis of the activating cytokines. “Classically activated” monocytes are activated by the Th1 cytokine IFN- γ , whereas alternatively activated macrophages are activated by the Th2 cytokines IL-4 and IL-13. Alternatively activated macrophages are proposed to be profibrotic, possibly by activating TGF- β . Alternatively activated macrophages have been classified into further subsets, and macrophages activated by type I IFNs also have distinctive features, thus indicating an expanding array of macrophage phenotypes. Monocytes from a subset of SSc patients show increased expression of IFN-regulated genes, whereas SSc patients complicated by PAH express genes associated with alternative macrophage activation, including *MRC1*, a gene highly upregulated by IL-13.

Thus, gene expression data implicate both IFNs and IL-13 in activating monocytes/macrophages in SSc patients, which suggests important roles of these cells in the pathogenesis of SSc.

Adaptive T-cell responses in fibrotic disease

Chronic sclerodermatous GVHD shows that adaptive immune responses can lead to autoimmunity and tissue fibrosis. Oligoclonal expansion of T cells in the skin of patients with SSc supports the importance of antigen-dependent T-cell expansion. Microchimerism secondary to persistent fetal cells has been proposed as a possible source of antigenic stimulus in SSc.^{36,37} Autoantigens, such as topoisomerase I, represent another possible target for oligoclonal T-cell expansion because T cells may be required for

Fig. 143.10 Vascular injury leads to vascular activation, injury, and apoptosis and might result from transient or latent viral infection; soluble mediators such as interferon- γ (IFN- γ), tumor necrosis factor- α , and angiotensin II (Ang II); autoantibodies; reactive oxygen species; and hypoxia. Hypoxia stimulates additional pathogenic factors such as inducible nitric oxide synthase, hypoxia-inducible factor-1, and endothelin-1 (ET-1). Transforming growth factor- β (TGF- β) or other factors might induce endothelial cells to transform into mesenchymal cells. Loss of perivascular pericytes disrupts vascular integrity. AECA, anti-endothelial cell antibody; HO, heme oxygenase; VEGF, vascular endothelial growth factor.

autoantibody production. Topoisomerase-specific T-cell clones have been identified in some antitopoisomerase-positive patients.³⁸

Vascular injury and vasculopathy in systemic sclerosis

Vascular involvement accounts for many of the clinical complications in SSc, and vasculopathy may be the primary event in SSc.³⁹ Vascular obliteration leads to hypoxia, which enhances collagen synthesis and fibroblast activation and is likely to further exacerbate the fibrotic response in SSc. Vasculopathy might result from several mechanisms, including stress-related injury, apoptosis, pericyte detachment, and endothelial-mesenchymal transformation (Fig. 143.10).

Endothelial cell injury

Activated endothelial cells play an important role in recruiting inflammatory cells through adhesion receptors. The adhesion molecules vascular cell adhesion molecule 1 (VCAM-1) and intercellular adhesion molecule 1 (ICAM-1) are upregulated in SSc skin, as is MHC class II, thereby providing a means for cognate endothelial interaction with T cells. Soluble markers of activated endothelium such as sVCAM, sICAM, and E-selectin are elevated in the circulation.

Endothelial cell apoptosis

Endothelial cell apoptosis is implicated in the UCD 200/206 chicken model of scleroderma. This model also showed evidence of dermal endothelial cell apoptosis in the dermal vessels of patients with early active SSc. Although electron microscopic findings in SSc are consistent with the notion of endothelial cell death, a recent study has questioned the importance of apoptosis in SSc vasculopathy based on lack of caspase-3 staining.

Cytotoxic factors in endothelial apoptosis

Increased circulating levels and skin expression of granzyme have been reported in SSc. Granzyme is a component of cytotoxic granules containing perforin and granzyme B. Cytotoxic T cells kill target cells through surface expression of Fas ligand (FasL), which engages Fas on target cells and triggers apoptosis. Cytotoxic T cells might mediate vascular injury via granzyme/perforin or Fas/FasL. Several viruses can infect endothelial cells and lead to apoptosis. In particular, hCMV can infect endothelial cells and stimulate neointimal changes in immunodeficient mice. Autoantibodies in SSc patients cross-reacting to a CMV protein can induce endothelial cell apoptosis.

Endothelial cell apoptosis appears to be highly dependent on the vascular bed affected. For example, TGF- β has diametrically opposed actions on pulmonary endothelial cells derived from the pulmonary artery and from the pulmonary microvasculature, which respectively inhibit and promote apoptosis. Isolated vascular involvement of distinct organs (lungs, digits, kidneys) in SSc patients suggests that mediators in different vascular beds have distinct responses to some underlying stimulus. In scleroderma renal crisis, renin and angiotensin II are highly upregulated by an unknown trigger. Angiotensin II, in turn, can stimulate endothelial cell apoptosis,⁴⁰ as well as fibrosis. However, disease in this vascular bed is not typically associated with ischemic digits or PAH, thus indicating that despite similar pathologic processes, different pathogenic mechanisms might be involved at different sites.

Vascular spasm, reactive oxygen species, and hypoxia

Ischemia-reperfusion occurs commonly in SSc associated with the Raynaud phenomenon (Fig. 143.11). Furthermore, there is evidence in SSc that spasm may contribute to disease in other vascular beds. However, most

Fig. 143.11 Basal vascular relaxation is maintained by nitric oxide (NO) produced from arginine by endothelial nitric oxide synthase (eNOS). NO relaxes vascular tone through smooth muscle guanylate cyclase and also inhibits endothelin-1 (ET-1). In cold-induced vasospasm, translocation of internal α_{2c} -adrenoreceptors to the cell surface leads to increased sensitivity to circulating adrenocorticoids such as norepinephrine (NE) and causes hypoxia. ET-1, strongly upregulated in systemic sclerosis (SSc), is secreted by endothelial cells and directed toward underlying smooth muscle cells. Angiotensin II (Ang II) is also a potent vasoconstrictor and induces the generation of reactive oxygen species (ROSs). Inflammatory mediators increase inducible nitric oxide synthase (iNOS) in tissues. NO in tissues can react with ROSs and thereby result in peroxynitrate and nitrated proteins.

studies suggest that underlying endothelial cell dysfunction is the primary cause of the increased vascular reactivity. The Raynaud phenomenon represents an exaggerated normal response to cold that is largely mediated by α_{2c} -adrenoreceptors to protect against heat loss. Cold exposure, possibly by enhancing the generation of ROSs, stimulates smooth muscle cell rho kinase, which results in translocation of internal α_{2c} -adrenoreceptors to the cell surface. Upregulation of α_{2c} -adrenoreceptors during stress could explain why patients with SSc show exaggerated cold-induced vasospasm.

Although vascular spasm is not generally considered the primary vascular event in SSc, the resulting ischemia-reperfusion injury might have profound effects on vascular cells. Hypoxia induces the expression of ET-1, VEGF, and PDGF; inhibits endothelial nitric oxide synthase (eNOS); and induces endothelial cell apoptosis. These effects are mediated largely through the transcription factor hypoxia-inducible factor-1 α (HIF-1 α). Hypoxia-induced ET-1 may serve to further exacerbate vasoconstriction. By stimulating the production of inflammatory cytokines, such as TNF- α , IL-1, and IL-6, reperfusion may also contribute to vascular injury. Thus, vasospasm, ischemia, and hypoxia result in the release of soluble mediators that amplify the vasculopathy in SSc.

Endothelium-dependent relaxation and nitric oxide

Nitric oxide (NO) synthase catalyzes the oxidation of L-arginine to equimolar quantities of NO and L-citrulline.⁴¹ Release of NO from the vascular endothelium represents a powerful vasodilator signal to the underlying smooth muscle (see Fig. 143.11). NO plays an important role in the regulation of cardiovascular, nervous, renal, and immune responses. Under physiologic conditions, basal NO generated by eNOS maintains normal vascular

vasodilatory tone. The target of NO in the vascular wall is the soluble guanylate cyclase in smooth muscle cells. Activation of guanylate cyclase leads to the accumulation of cyclic guanosine monophosphate, which triggers smooth muscle relaxation and vasodilatation. In SSc, deficient endothelium-dependent relaxation is suggested by impaired maximal responses to endothelial-dependent vasodilators and normal responses to endothelial-independent dilators. This impairment is associated with an increase in the markers of endothelial cell injury and decreased eNOS in the skin. The consequences of impaired endothelial NO release include defective control of vascular tone. Because NO inhibits platelet aggregation and is a potent chemical barrier protecting endothelial cells from oxidation injury, the impaired NO production associated with endothelial cell dysfunction may contribute to further vascular injury.

Paradoxically, despite the loss of eNOS and endothelial-dependent vasodilatation, several studies have shown increased levels of circulating NO in SSc. This may reflect increased expression of inducible NOS (iNOS) as the vascular damage proceeds. iNOS can be induced by lipopolysaccharide, IFN- γ , IL-1, and other inflammatory signals in a wide range of cell types, including macrophages, and its primary role appears to be regulation of immune functions. However, the effect of increased NO in tissues can potentially be deleterious by reacting with superoxide anion to produce peroxynitrate. Increased levels of nitrated proteins in SSc skin suggest that NO might contribute to tissue injury in SSc.

Endothelin-1

ET-1 and its ET-2 and ET-3 isoforms mediate endothelium-dependent vasoconstriction and are potent mitogens for smooth muscle cells and fibroblasts. ET-1 is a 21-amino acid linear peptide produced from a prepropeptide that is converted to the mature protein by an endothelin-converting enzyme. Thrombin, epinephrine, TNF- α , TGF- β , angiotensin II, and hypoxia can all stimulate the release of ET-1 from endothelial cells. Increased plasma ET-1 levels have been associated with the Raynaud phenomenon and SSc, particularly the diffuse cutaneous subset with associated PAH, pulmonary fibrosis, and scleroderma renal crisis. Increased ET-1 accumulation and ET-1 receptor expression are seen in skin and lung tissue from patients with SSc.⁴² The critical role of ET-1 in SSc vascular disease is illustrated by the efficacy of the endothelin receptor antagonist bosentan in the prevention of ischemic digital ulcers and in improvement of symptoms of PAH.⁴³ ET-1 also enhances fibroblast proliferation and the synthesis of types I and III collagen and decreases the expression of collagenase (matrix metalloproteinase-1).

Intimal hyperplasia

Hyperplasia of the intimal layer of small to medium-sized arteries is a distinguishing pathologic hallmark of SSc. The cells responsible for intimal hyperplasia might arise from endothelial cells, smooth muscle cells, or pericytes (Fig. 143.12). Similar pathologic changes are seen in most forms of PAH, where myofibroblasts are implicated as the cells making up the hyperplastic neointima. One report showed neointimal cells in SSc-associated PAH to be derived from endothelial cells based on factor VIII antigen staining. In the skin, endothelial cell markers, notably VE-cadherin, are absent, whereas smooth muscle actin staining is increased, thus supporting a myofibroblastic phenotype in neointimal lesions. Myofibroblast accumulation on the neointimal lesions might derive from several sources. Markers for pericytes are increased in SSc vasculature, which suggests that pericytes might be responsible for the intimal hyperplasia. Alternatively, neointimal cells might derive from vascular smooth muscle, circulating progenitors, or endothelial cells.

Endothelial-mesenchymal transformation

An alternative explanation for vascular pathology and neointimal formation in SSc is endothelial-mesenchymal transformation, a normal developmental process in which endothelial cells in the developing heart transition into mesenchyme in the atrioventricular and outflow tract but not in the

Fig. 143.12 Two cell types have most frequently been implicated in the intimal hyperplasia in systemic sclerosis. Some data support endothelial cells as the primary cell source for neointima, with hyperplasia of this normally single cell layer. Other data more strongly implicate pericytes in hyperplasia of these cells and endothelial cell apoptosis. The resulting lesion is an obliterative vasculopathy. SM, smooth muscle.

ventricular endothelium. Mature endothelial cells can be induced by TGF- β to undergo a similar transition *in vitro*, as demonstrated by the loss of endothelial cell markers such as platelet-endothelial cell adhesion molecule (PECAM) and the acquisition of mesenchymal markers such as α -smooth muscle actin. Endothelial-mesenchymal transformation contributes to cardiac fibrosis in a murine model.

Circulating endothelial cells and vascular progenitor cells

Circulating endothelial cells are mature cells that are shed from blood vessels, are normally present in only very low numbers, but are increased in a variety of vascular diseases, in which they appear to be markers of vascular damage. Circulating endothelial cells are increased in SSc, consistent with the known vascular injury. In contrast, circulating endothelial progenitor cells arise from the bone marrow and contribute to vascular repair. Reports on circulating endothelial progenitor cells in SSc have been conflicting, with both increased and decreased numbers being described. Circulating vascular progenitor cells have promise as potential therapeutic tools for the repair of damaged vessels.

Platelet activation and coagulation

Platelet activation and abnormalities in the coagulation system are often prominent in SSc. Elevated plasma levels of the platelet-specific proteins β -thromboglobulin and platelet factor 4 have been proposed as markers of progression from primary Raynaud phenomenon to SSc. Platelet activation in SSc might occur secondary to endothelial dysfunction and contribute to the occlusive arterial disease by release of PDGF, TGF- β , and serotonin, which also have an impact on fibrosis. The prominent microvascular thrombosis and enhanced intravascular fibrin deposition in SSc suggest defective endothelial control of coagulation and fibrinolysis. Defects in endothelial cell regulation of thrombosis and fibrin deposition may thus contribute to the intimal hyperplasia in SSc.

Management of systemic sclerosis

■ VIRGINIA D. STEEN

- Effective management of systemic sclerosis (SSc) depends on secure diagnosis and subset classification determined from autoantibody status, the stage of disease, extent of organ-based complications, and the presence of overlap features.
- SSc patients should undergo regular screening for cardiopulmonary complications, even if asymptomatic. Clinical, serologic, and genetic factors may allow individualization of serial investigations in the future.
- Therapies that target the immune system and vasculature have been shown to be effective in placebo-controlled studies.
- Effective treatments for organ-based complications are emerging, especially for scleroderma renal crisis, pulmonary interstitial fibrosis, and pulmonary hypertension.
- Better understanding of the pathogenesis of SSc is likely to lead to the development of targeted approaches to attenuate key mediators of signaling pathways.

INTRODUCTION

The management of systemic sclerosis (SSc) is a major challenge that should be approached with a thorough understanding of current concepts of pathogenesis, the clinical features including classification and natural history, and an appreciation that there is much to be offered to patients. It is necessary to take a systematic approach to diagnosis and evaluation in each case to provide appropriate treatment. Many of the organ-based complications of SSc are treatable, if not curable. In particular, therapeutic advances in management of other medical conditions have been extrapolated to SSc. Angiotensin-converting enzyme (ACE) inhibitors developed for the treatment of hypertension dramatically changed the disease course and survival in scleroderma renal crisis, a previously deadly complication.¹ One-year survival rates of patients with scleroderma renal crisis went from 10% to 70% after this drug became available. Drugs that have less dramatic effects on overall survival but are equally important in terms of morbidity are calcium channel blockers, which were developed for hypertension but help Raynaud phenomenon, and proton pump inhibitors, which were developed to treat common hyperacidity and help the esophagitis resulting from esophageal dysmotility. These drugs have significantly improved the management of two of the most frequent and bothersome symptoms in scleroderma.

Classically, the disease has been divided into limited and diffuse cutaneous scleroderma, but prognosis and management are more importantly affected by the stage of disease, the autoantibody subset, and the type of organ involvement. Staging and subsetting are particularly important in scleroderma because patients have different levels of risk of experiencing the different manifestations of scleroderma during the course of their illness. The disease stage—early disease, chronic stable disease, or late-stage disease—is important when considering what aspects of the disease have the potential to be responded to available therapies. Autoantibody testing has been very helpful in identifying patients who are at risk of specific types of organ involvement.² Thus disease-modifying agents directed at the skin should be used primarily in patients with early disease (symptoms for less than 5 years) who have antitopoisomerase (anti-Scl-70), anti-RNA polymerase III, or an antinuclear antibody (ANA) with a nucleolar pattern. (Tests for the nucleolar-pattern ANAs anti-U3-RNP and anti-Th/To are not commercially available, but these antibodies are identified as an ANA with a nucleolar pattern on immunofluorescent assays). Patients with antitopoisomerase antibodies and nucleolar antibodies are at high risk of severe

pulmonary fibrosis, which needs to be treated aggressively even though these patients may have only limited cutaneous skin disease. Patients with the anticentromere antibody are the only patients with limited scleroderma who are not at risk of severe fibrosis and heart and kidney involvement, but they are at increased risk of isolated pulmonary arterial hypertension. On the other hand, patients with severe diffuse cutaneous disease with antibodies to RNA polymerase III are much less likely to develop severe lung disease but have an extremely high risk of renal crisis (25%).

Severe organ involvement, particularly pulmonary fibrosis, renal crisis, and cardiac involvement, occurs most often during the first 5 years in patients with diffuse scleroderma.³ Therefore if by 5 years such a patient does not have evidence of severe involvement of these organs, the patient has a decreased likelihood of developing these abnormalities during the remainder of the illness. However, any patient can have symptoms related to Raynaud phenomenon, digital ulcers, muscle or joint involvement, calcinosis, or esophageal or other gastrointestinal involvement throughout the entire course of the illness. Pulmonary arterial hypertension most frequently occurs late in the illness, and although it is most common in patients with limited cutaneous disease with anticentromere antibodies, it also occurs in some diffuse scleroderma patients with nucleolar-pattern ANAs.

Despite many advances and increasing numbers of clinical trials addressing scleroderma, unfortunately there still are no treatments that have been shown in a controlled clinical trial to modify mortality. However, over the last 10 years, our experience with clinical trial methodology has given us an appreciation of what has to be done to demonstrate effectiveness. The emergence of a number of attractive potential therapeutic agents that target key pathways in SSc pathogenesis make such treatment a real possibility in the foreseeable future.

PRINCIPLES OF EFFECTIVE MANAGEMENT

Clinical heterogeneity is a hallmark of scleroderma and ranges from prescleroderma or possible scleroderma (the presence of Raynaud phenomenon plus SSc-associated autoantibodies) at one end to rapidly progressive diffuse cutaneous SSc with multiorgan failure at the other. Between these extremes lie limited cutaneous SSc with and without organ involvement, diffuse cutaneous disease with less rapidly progressive skin manifestations but more organ involvement, and extensive diffuse cutaneous disease without organ involvement. Additionally, patients can have overlap syndromes with features of other autoimmune rheumatic disorders, most commonly polymyositis and Sjögren syndrome but also rheumatoid arthritis and systemic lupus erythematosus. These overlap syndromes often present major management challenges because there may be different levels of activity among the various disease components. Clearly not all patients require the same level of investigation or therapeutic intervention. Each patient requires an individual approach to the disease with evaluation and treatment of all appropriate problems.

Optimal management of SSc requires the following (Fig. 144.1):

- Establishing an accurate diagnosis at the earliest opportunity
- Staging disease by onset and rate of symptom progression and determining subset based on autoantibodies and organ system involvement so that appropriate screening, organ diagnosis, and treatment can be achieved in every patient
- Addressing all potential problems through early identification, appropriate therapy, and aggressive intervention for the more serious organ problems
- Educating patients regarding their own risk factors and prognosis and allowing them to participate in treatment with a holistic approach that recognizes the impact of the disease on lifestyle and relationships

Fig. 144.1 Management in scleroderma requires multiple strategies depending on the specific problems that are present in individual patients. ACE, angiotensin-converting enzyme; NSAIDs, nonsteroidal antiinflammatory drugs.

Many manifestations require treatment throughout the course of the disease, based primarily on the symptoms that almost all patients have, such as Raynaud phenomenon; esophageal reflux; arthralgias, arthritis, and tendon involvement; fatigue; and sicca symptoms. These define the background therapy for all SSc patients. Identification of organ involvement requires additional testing, which, along with the stage of the disease, is helpful in determining the degree of disease activity and damage as well as the appropriate treatment. A noninflammatory myopathy or fibrotic arthropathy is treated differently from an inflammatory process. In some situations, identification of abnormalities in organ systems may not lead to any specific therapy but will help focus the timing of further screening or allow early intervention or treatment of associated problems. In general, to treat the whole scleroderma patient, it is important to remember that the whole is the sum of all the different components. Dissecting each potential involvement and making a decision about whether treatment, observation, or future screening is necessary allows the most optimal treatment for all scleroderma patients.

CLINICAL TRIALS IN SYSTEMIC SCLEROSIS

Difficulties in conducting clinical trials in scleroderma are well recognized. The clinical heterogeneity and variable natural history together with a paucity of global assessment measures have made performing clinical trials in SSc challenging.⁴ Other problems include absence of any treatment of proven efficacy to use as a comparative active control arm and understandable reluctance by both patients and their physicians to consider entering a placebo-controlled study involving a potentially life-threatening disorder. In particular, skin sclerosis has been found to be an unreliable measure of disease progression, in part due to its tendency in a cohort to improve over time after the first 12 to 18 months of disease. Thus in most reported placebo-controlled trials there has been improvement in skin score over time in the placebo-treated patients. Alternative approaches include longer-term studies with a time-to-event design and studies using organ-based endpoints

such as markers of lung function or functional capacity that reflect pulmonary disease. The first major study that has shown a statistically significant benefit in scleroderma is the study comparing cyclophosphamide with placebo in pulmonary fibrosis (Scleroderma Lung Study).⁵ Similarly, the recently completed studies examining prostacyclins and endothelin receptor antagonists as treatments for pulmonary arterial hypertension in scleroderma were major studies with positive results even though they were focused primarily on idiopathic pulmonary hypertension.⁶ These studies are among the very first trials in SSc that show both statistically positive results and are clinically meaningful. There is extensive international cooperation in the area of clinical trials,⁷ facilitated by the international Scleroderma Clinical Trials Consortium, which maintains a database of currently recruiting studies (details at <http://www.sctc-online.org>).

DISEASE-MODIFYING THERAPIES FOR SYSTEMIC SCLEROSIS

Few of the agents currently used as disease-modifying treatments for scleroderma-spectrum disorders have undergone rigorous placebo-controlled evaluation, and the results for those which have are mostly disappointing. No agent has been shown to be of unequivocal benefit, and even if such data were available, therapeutic gain must be carefully balanced against toxicity and considered in the context of the natural history of the condition. It may not be justifiable to use treatments with potentially serious adverse effects in patients with some scleroderma subsets such as limited cutaneous SSc, or even stable late-stage diffuse disease. It is likely that organ-based treatment strategies directed toward complications such as renal disease, pulmonary hypertension, or fibrosing alveolitis will have more immediate effect on mortality than the development of generalized disease-modifying strategies. Disease-modifying approaches can be classified according to the underlying pathogenic process that they target, including immunomodulatory and antifibrotic therapies (Table 144.1).

TABLE 144.1

Evidence based review of immunomodulatory and antifibrotic strategies for disease-modifying treatment of systemic sclerosis

Agent	Clinical trial data	Study	Grade*
Immunomodulatory agents			
Cyclophosphamide	Double-blind placebo-controlled trials examining use in SSc-associated pulmonary fibrosis	5, 9	A
Methotrexate	Placebo-controlled trial, 30 patients; significant improvement in skin score	10	A
	Larger North American study; inconclusive results	11	A
Mycophenolate	Favorable outcomes in skin, lung, and survival rate in uncontrolled trials and observational cohorts	12-14	B
Rituximab	Small, open, randomized trial showed favorable skin and lung outcomes, but prospective open study found no effect on skin	16, 17	A
		15	B
Immunoablation	Small short-term study comparing stem cell transplantation with high-dose intravenous cyclophosphamide (Cytosan); very favorable results	21	A
	Ongoing long-term studies USA and Europe	19, 20	C, A
Cyclosporine	Open study, 10 patients; improvement in skin score	23	C
Intravenous immunoglobulin	Improved skin and joint in open study	24	C
Extracorporeal photopheresis	First study suggested benefit but later evaluation equivocal	25	A
Oral induction of tolerance to type I collagen	Favorable pilot data; trial results positive for late-stage disease	26	A
Rapamycin	Small randomized study, no difference compared with methotrexate	27	A
Anti-tumor necrosis factor agents	Open-label study; variable effect on skin, good effect on joints	28	C
Antifibrotic agents			
Interferon- α	No difference with treatment, considered ineffective	29	A
Interferon- γ	Several uncontrolled studies with variable outcomes	30	C
D-Penicillamine	Uncontrolled studies with positive effects but controlled trial without evidence of response	31	B
		32	A
Relaxin	Phase 2 study promising but large phase 3 study negative; considered ineffective	33	A
Minocycline	Small open study with cured patients but larger uncontrolled study showing no effect	69	C
		34	B
Halofuginone	Plant alkaloid that downregulates collagen production in animal models of fibrosis; pilot study in scleroderma with positive results	70	C
Pirfenidone	Encouraging data in lung fibrosis but no formal study in scleroderma	35	A
Tyrosine kinase	Variable effects in several uncontrolled inhibitor trials showing increased toxicity	37, 38	B

*Findings of studies include this type of evidence:

Level A: Randomized Controlled Clinical Trial, cohort study.

Level B: Retrospective Cohort, Exploratory Cohort, Outcomes Research, case-control study; or extrapolations from level A studies.

Level C: Case-series study or extrapolations from level B studies.

Level D: Expert opinion without explicit critical appraisal; or based on physiology, bench research, or first principles.

Immunomodulatory strategies

Cyclophosphamide

Cyclophosphamide, an immunosuppressive drug of proven efficacy in the management of a number of autoimmune rheumatic diseases, has been reported to be effective for SSc-associated lung fibrosis.⁸ Recently two major clinical trials evaluating cyclophosphamide in scleroderma-associated pulmonary fibrosis have been completed, a North American study evaluating oral cyclophosphamide⁵ and a UK study examining intravenous administration of the drug.⁹ Both showed a significant advantage for cyclophosphamide over placebo, although clinical benefit was modest. One of these studies also examined other aspects of SSc using the Scleroderma Health Assessment Questionnaire and skin score and suggested a more extensive benefit for cyclophosphamide. However, toxicity must be carefully balanced against efficacy. Premature ovarian failure, opportunistic infections, and the possibility of late secondary malignancies are important considerations in planning the route, dosage, and duration of cyclophosphamide administration.

Methotrexate

Methotrexate was studied in a small trial in the Netherlands¹⁰ that included 29 patients and was placebo controlled for 24 weeks followed by a 24-week open-label continuation in those patients who had shown an apparent response. This trial suggested benefit in terms of skin score and lung function test results. A substantially larger study conducted in North America has been reported. Although a minor advantage for active treatment over placebo was observed for skin sclerosis score, this was below the level considered clinically meaningful.¹¹ However, this trial was statistically

underpowered due to recruitment difficulties. Both studies used a 15-mg dose of methotrexate. The drug's usefulness in inflammatory myositis and arthritis can be just as great as in the other connective tissue diseases.

Mycophenolate mofetil

Mycophenolate mofetil (MMF) is an antiproliferative immunosuppressive agent indicated for prevention of acute renal, cardiac, and hepatic transplant rejection. An open-label prospective study examined the use of 2 to 3 g of MMF daily for treatment of scleroderma, and some improvement in skin thickening was noted in patients with early diffuse scleroderma¹² compared with historical controls. However, in a large retrospective series 109 patients failed to show any improvement in skin score, although investigators did identify a survival improvement.¹³ Double-blind placebo-controlled trials examining the use of MMF to treat scleroderma skin manifestations have been very challenging and difficult to perform, and thus such a trial has not been done. Additional studies have focused on lung function and have shown promising effects with stabilization of lung function.¹⁴ MMF was well tolerated and there is an on-going controlled trial comparing MMF with cyclophosphamide primarily for treatment of interstitial fibrosis, but other disease aspects including skin manifestations will be evaluated.

Rituximab

Rituximab, a monoclonal anti-CD20 antibody that depletes CD20 expressing B lymphocytes, is increasingly being used to treat autoimmune disease. Initially used in immune-mediated cytopenias and lupus, it is now approved for treatment of rheumatoid arthritis and vasculitis. An open-label study involving 13 patients with early scleroderma showed little change in skin scores over a year.¹⁵ A recent small randomized study (eight treated patients

and six control subjects) looked at the use of rituximab in scleroderma patients with interstitial fibrosis.¹⁶ Two cycles (375 mg/m² weekly of intravenous rituximab for 4 weeks) were administered at baseline and at 6 months, and there was significant improvement in skin fibrosis as well as forced vital capacity and diffusing capacity in treated patients compared with untreated patients during the 1-year study. Continued stabilization occurred in these patients with retreatment over a 2-year period.¹⁷ In a prospective study Boselo and colleagues¹⁸ administered rituximab to nine patients with diffuse scleroderma who had shown no response to cyclophosphamide; these patients experienced a 43% improvement in skin score. A prospective controlled trial of rituximab is ongoing but is focused on joint manifestations.

High-dose immunosuppression with autologous peripheral stem cell transplantation

One of the most aggressive approaches to therapy for SSc is the use of immunoablation followed by reconstitution using autologous peripheral stem cell transplantation. The rationale for this therapy is similar to that for its use in other autoimmune diseases. Thus, if SSc is being driven by an autoimmune process, then ablation of autoreactive lymphocyte clones may block pathogenesis. If the immune system is reconstituted in the presence of the neoantigens responsible for autoimmunity then tolerance will be reestablished. However, even if such reestablishment of tolerance does not occur, it is still plausible that the intensive immunosuppression during this treatment will be directly beneficial. A variety of methods of mobilization and conditioning have been used for this treatment. Open-label studies at the Fred Hutchinson Cancer Center and the European Bone Marrow Transplant Registry have consistently shown very dramatic and rapid improvement in skin thickening.¹⁹ Most patients experience more than a 25% improvement in the first 6 months after the procedure. However, the long-term effect on organ systems is still unclear. There are patients who develop new organ abnormalities or a recurrence of aggressive disease after one of these transplants. Patients must be carefully screened at baseline to make sure they can tolerate the transplant-related morbidity, which may be life-threatening, and to determine if they have irreversible organ system disease, so only a small subset of patients would be eligible.²⁰

A recent single-site, small, randomized, controlled study (the ASSIST trial) compared stem cell transplantation with cyclophosphamide therapy. Patients undergoing stem cell transplantation showed significant improvement in skin and lung function over 2 years with no deaths from either severe disease or toxicity of the treatment.²¹ Cyclophosphamide treatment failed in eight of the nine patients receiving it, and seven of these patients crossed over to stem cell transplantation and also showed improvement. However, this study was quite small and included patients with milder disease, and the 2-year duration may have been too short to know whether recurrence of progressive disease will occur. Two large, randomized, controlled trials are currently under way: the Autologous Stem Cell Transplantation International Scleroderma Trial (ASTIS) in Europe and the Scleroderma, Cyclophosphamide or Transplant (SCOT) trial in the United States. Both are comparing stem cell transplantation with monthly pulse cyclophosphamide using similar assessment protocols so that data from these studies may ultimately be combined.

Cyclosporine

Because it suppresses T-cell activation, cyclosporine (cyclosporin A) has attractive properties for treating SSc, especially cases of aggressive diffuse cutaneous SSc in which there is marked immunologic activation. The main problem, however, has been toxicity. For scleroderma there are particular risks, especially from nephrotoxicity. One series found three of eight SSc patients treated with cyclosporin developed renal crisis and they thought that the rate of renal crisis in SSc patients treated using cyclosporine may be twice the expected rate.²² An open-label study of 48 weeks of cyclosporine administration suggested efficacy, although there was significant toxicity, especially at dosages above 3 to 4 mg/kg/day.²³ Tacrolimus, a drug in the same family, also has significant nephrotoxicity, which precludes its routine use in SSc.

Intravenous immunoglobulin

The use of pooled plasma of human polyclonal immunoglobulin G (IVIG) to treat SSc has been reported in several open studies. Usually 2 g/kg of IVIG were given over 2 to 4 days each month for 6 months. These open-label pilot studies have shown encouraging results, although they included patients with disease of variable duration and stage, so interpretation must be guarded.²⁴ Prospective studies are needed to determine its effectiveness in SSc.

Plasmapheresis and photopheresis for diffuse cutaneous scleroderma

Trials of plasmapheresis combined with immunosuppressive therapy were conducted more than 20 years ago, and this regimen was considered to be helpful in cases of diffuse cutaneous SSc; however, this combination has never been thought to be a realistic treatment for scleroderma. Another immunosuppressive strategy is extracorporeal photopheresis following sensitization of host leukocytes by methyl psoralen. In view of the presence of an infiltrate of active immune cells in early SSc, especially the diffuse cutaneous subset, there was a plausible theoretical basis for this mode of treatment. A clinical trial using a sham photopheresis control showed a significant improvement in skin and joints from baseline in treated patients, but this improvement was not statistically different from the results in control patients.²⁵

Tolerance to human type I collagen

In a disease whose pathologic hallmark is increased extracellular matrix deposition it is somewhat surprising that oral type I collagen administration is being proposed. The rationale is based on the observation that oral tolerance to type I collagen can be induced and the hypothesis that there may be an autoimmune reaction to collagen in SSc contributing to local production of cytokines and that induction of regulatory lymphocytes through establishment of oral tolerance may have a beneficial effect by modulating other cell types involved in disease pathogenesis. There are some experimental data supporting this approach, and results of a controlled trial were recently reported showing encouraging trends, particularly in late-stage scleroderma.²⁶ This treatment strategy has the advantage of apparently being safe, and it also may be effective in established disease, which is otherwise difficult to treat.

Other potential immunotherapies

Rapamycin, a macrolide antibiotic with antifungal and antitumor properties, inhibits interleukin 2–dependent T-cell proliferation. A small, randomized, single-blind study failed to find any difference between rapamycin and methotrexate in treatment of SSc, and the rapamycin-treated patients had significant toxicity.²⁷ Tumor necrosis factor- α antagonists have been used in the treatment of scleroderma.²⁸ Infliximab therapy for scleroderma was examined in an open-label study and was associated with some improvement in the Rodnan skin score, but the difference was not thought to be statistically significant. However, its use in scleroderma patients with an inflammatory polyarthritis was successful in controlling the joint symptoms.

Antifibrotic strategies

Interferons

Interferons (α , β , or γ) exert pleiotropic effects on fibroblasts *in vitro*, including downregulation of extracellular matrix gene expression. This led to the hope that the interferons might have antifibrotic activity *in vivo*. There were a number of encouraging pilot studies, and these prompted more extensive evaluation of interferon- γ and interferon- α . A placebo-controlled trial of interferon- α for treatment of early diffuse cutaneous SSc was undertaken in the United Kingdom.²⁹ However, a higher mortality and no benefit for skin manifestations or lung function were found in the active-treatment arm. Phase 2 studies of interferon- γ have suggested a modest benefit for skin sclerosis. There was a controlled trial that showed similar findings, but the patients had disease of very long disease. Overall, it is disappointing that interferons have not fulfilled their early promise; whether they will ultimately have any place in scleroderma treatment remains uncertain. A meta-analysis of recent studies examining the use of interferon- γ in idiopathic lung fibrosis showed improved survival in the treated patients.³⁰ This has prompted reexamination of this important group of biologic therapeutic agents.

D-Penicillamine

D-Penicillamine is a chelating agent that blocks the intramolecular and intermolecular cross-linking of collagen; this makes it a good potential antifibrotic agent, although as an earlier treatment for rheumatoid arthritis it showed some immune-modifying qualities as well. Multiple uncontrolled studies with large numbers of patients showed impressive improvement in the skin score in patients with early rapidly progressive scleroderma as well as a possible decrease in the occurrence of renal crisis and improved survival.³¹ However, there was an excellent double-blind controlled trial that failed to show any difference between high-dose and low-dose D-penicillamine.³² This trial included patients with early diffuse disease, but

they had milder, less aggressive disease than the patients in the earlier uncontrolled trials. Patients in the controlled trial had a mean skin score of 20 (out of a possible 51) at the start of the study, which decreased to 17 after 2 years of treatment. In contrast, patients in the uncontrolled trials had more severe disease at onset, beginning with a skin score of 28, which increased to 33 and then decreased to 17 after 2 years. It is unlikely that any further studies will be done, so it will not be known whether there is a subset of patients who have a more impressive response to this drug.

Recombinant human relaxin

Another agent studied is recombinant human relaxin. This hormone, normally present in significant amounts only in pregnant women, appears to have benefit in SSc. *In vitro* studies suggest that relaxin reduces synthesis of type I collagen by scleroderma fibroblasts, and a dose-escalating placebo-controlled trial has shown benefit based on self-report health assessment questionnaires. Although this treatment approach appeared very promising, a large phase 3 trial in North America yielded negative results, and this agent is no longer under active consideration.³³

Minocycline

Another drug that was initially examined in a very small study is minocycline. This agent has some possible antifibrotic properties in addition to being an antibiotic. The pilot uncontrolled study of 10 patients treated with minocycline was widely reported in the lay press, and results suggested dramatic responses to this drug. A larger open-label clinical trial in patients with diffuse scleroderma failed to show any significant improvement in skin scores after the use of minocycline.³⁴

Pirfenidone

Pirfenidone blocks activation of transforming growth factor- β (TGF- β), suppresses elevation of lung basic fibroblast growth factor, and prevents bleomycin-induced decrease in lung interferon- γ levels. Pirfenidone has demonstrated positive effects in both a pilot study and a phase 2 double-blind trial in idiopathic pulmonary fibrosis. These studies have shown promising results, although the controlled trial had some methodologic problems. Results from several phase 3 trials have recently been reported showing significant delay in deterioration in pulmonary function, and these findings led to approval of the drug for treatment of idiopathic pulmonary fibrosis in Europe and Japan; however, the U.S. Food and Drug Administration (FDA) has required an additional study.³⁵ Pirfenidone has not been tried in scleroderma.

Tyrosine kinase inhibitors

Imatinib mesylate is a small-molecule tyrosine kinase inhibitor that binds to the adenosine triphosphate binding pocket of Abelson kinase (c-abl) and efficiently blocks its tyrosine kinase activity; c-abl is an important downstream signaling molecule of TGF- β . Recent studies suggest that imatinib mesylate strongly inhibits the synthesis of major extracellular matrix proteins by fibroblasts from SSc patients. Treatment with imatinib mesylate efficiently reduced the development of fibrosis in animal models of fibrosis. The potent antifibrotic effects *in vitro* and *in vivo* in animal models, as well as the good clinical experience in other diseases, have led to multiple clinical trials of the use of imatinib mesylate in scleroderma and other fibrotic states. Hinchcliff³⁶ demonstrated impressive effects of imatinib mesylate on scleroderma fibroblasts *in vitro*. The largest of the open-label trials included 30 scleroderma patients and showed an improvement in the modified Rodnan skin score from baseline as well as some improvement in lung function.³⁷ Patients experienced a lot of toxicity, but it was manageable. Another study used a higher dose that produced unacceptable toxicity.³⁸ A small, controlled trial was unable to show significant improvement in modified Rodnan skin scores or skin biopsy findings in patients treated with imatinib mesylate.³⁹ Several other small, open-label studies in scleroderma focusing on skin or lung for which results have been presented in only abstract form have failed to show significant improvement with tyrosine kinase inhibitors. It is unclear whether the toxicity of the tyrosine kinase inhibitors will prevent further studies in subsets of patients.

Other potential antifibrotic agents

TGF- β is thought to be a key factor in the fibrogenesis in SSc. It promotes fibroblast activation and stimulates collagen synthesis.⁴⁰ The powerful profibrotic activity of this growth factor *in vitro* suggests that blockade *in vivo* may have a potent antifibrotic effect. Blocking strategies that have been used in preclinical animal studies include the use of neutralizing antibodies, recombinant soluble receptors, and small-molecule inhibitors of downstream signaling intermediates. Other exciting potential agents include blockers of connective tissue growth factor⁴¹; histone deacetylase 7;

rosiglitazone, which prevents cell differentiation and progression of fibrosis through the transcription factor peroxisome proliferator-activated receptor- γ ; and tocilizumab, a potent inhibitor of interleukin-6, which seems to play a major role in fibrosis in scleroderma and scleroderma animal models.

ORGAN-BASED ASSESSMENT AND TREATMENTS

Progress in managing organ-based complications has been made primarily by drawing an analogy with other medical disorders such as peptic ulcer disease, systemic hypertension, idiopathic pulmonary fibrosis, and pulmonary hypertension. As with many other chronic diseases a multidisciplinary approach to therapy is useful to address patients' physical, emotional, and social requirements as well as their medical problems. Physical therapy and aggressive exercise programs to maintain finger function, prevent joint contractures, and improve strength is extremely important, particularly because the treatment of skin disease is not satisfactory. The natural history of the disease is associated with some improvement in skin thickening, but if there are severe contractures, skin softening will not improve function. Patient education with careful explanation of the disease and its complications is integral to the successful management of the disease. Specialist nurse-educators, telephone help lines, and patient support organizations all have a valuable place in management. Although organ involvement is closely correlated with the stage and subset of the disease, treatments for the specific problems are similar across all subtypes of scleroderma.

Raynaud phenomenon

The most frequent manifestation of scleroderma is episodic peripheral vasospasm (Raynaud phenomenon), present in 95% of cases. Although many studies have confirmed the efficacy of vasodilators in primary Raynaud phenomenon, treatment of scleroderma-associated vasospasm is much more difficult. Calcium channel blockers are a standard treatment, but a recent evidence-based review of the treatment of scleroderma-related Raynaud symptoms found evidence of efficacy for α -blockers, ACE inhibitors, angiotensin II receptor antagonists, antithrombotics and inhibitors of platelet aggregation, biofeedback, hand exercises, relaxation therapy, serotonin reuptake inhibitors, smoking cessation, and warming of the hands and feet (Table 144.2).

There is considerable evidence implicating reactive oxygen species in the pathogenesis of SSc. Indirect support comes from studies showing reduced levels of micronutrient antioxidants in SSc patients and increased susceptibility of serum lipoproteins to oxidation. Further evidence is provided by increased levels of oxidative metabolites of prostaglandins in SSc patients. It has been suggested that oxidative fragmentation of hallmark antigens to reveal cryptic epitopes may provide a mechanistic link between the vascular and immunologic features of SSc. With this background several studies of antioxidant agents have been undertaken. Unfortunately, a recent review of complementary and nutritional therapies including probucol, vitamin E, and ascorbic acid could not confirm any significant effect of these types of treatment in scleroderma and Raynaud phenomenon.

There are a variety of pharmacologic treatments for the management of Raynaud symptoms. Calcium channel blockers remain the first-line agents for Raynaud phenomenon but frequently are not tolerated because of the vasodilatory effects of lowered blood pressure, headache, and peripheral edema.⁴² Angiotensin blockers and 5-hydroxytryptamine antagonists have been shown to be helpful in clinical trials, but a long-term controlled trial using the ACE inhibitor quinapril found it ineffective.⁴³ There are anecdotal reports that antiplatelet agents such as clopidogrel may be helpful in some patients with severe scleroderma-associated vasculopathy, although aspirin has not been shown to be helpful.

The most serious complication of Raynaud phenomenon is critical digital ischemia and ulceration. This is likely due to structural vascular disease as well as vasospasm. Sildenafil, a phosphodiesterase inhibitor (20 mg three times a day), and tadalafil can be particularly helpful in hastening healing of these ulcers.^{44,45} Intermittent infusions of prostacyclin or its analogues have been shown to be effective but they are costly and not available in the United States.⁴⁶ Orally active formulations of prostacyclin or its analogues are an attractive option, but unfortunately two large studies recently published in Europe and North America have failed to conclusively demonstrate efficacy. A pilot study showed the effectiveness of subcutaneous treprostinil, a potent prostacyclin used in pulmonary hypertension, and an oral preparation is now being studied for treatment of digital ulcers in scleroderma.⁴⁷ Bosentan, a dual-specificity endothelin receptor antagonist also used in pulmonary hypertension, has recently been shown in two large studies to prevent the development of new ischemic digital ulcers in scleroderma,

■ **TABLE 144.2**
Vascular therapies for Raynaud phenomenon

Treatment	Examples	Comments	Study	Grade*
Nondrug	Hand warmers, protective clothing	Universally helpful.		
Nutritional	Evening primrose oil	Symptoms improve.		
	Fish oil capsules	Symptoms improve only in primary Raynaud, not scleroderma.		
	Antioxidant vitamins	Theoretical benefit but no controlled trial evidence.	71	C
Pharmacologic for Raynaud phenomenon				
Calcium channel blockers	Nifedipine, amlodipine, diltiazem	Variable and differential response to different agents. Slow titration of dose reduced the severity of adverse effects.	42	A
Angiotensin-converting enzyme inhibitors (quinipril)		No evidence of effectiveness.	43, 72	A
Angiotensin receptor blockers	Losartan	Effective in clinical trial, but limited effectiveness in practice.	68	A
5-HT antagonists	Ketanserin	5-HT receptor antagonist; limited availability.	73	A
Selective serotonin reuptake inhibitor	Fluoxetine	Readily available; clinically less effective, but fewer vasodilatory adverse effects than with calcium channel blockers.	74	A
Treatment for ulcer healing				
Phosphodiesterase inhibitors	Sildenafil, tadalafil	Clinical trials show improvement in Raynaud manifestations and ulcer healing.	44, 45	A
Parenteral vasodilators	Iloprost, prostaglandin E ₁ , treprostinil	Effective in healing ulcers and reducing severity and frequency of Raynaud attacks. Expensive with limited long-term benefit.	46 47	C B
Endothelin receptor antagonists	Bosentan	Clinical trials show decreased new ulcers (approved for ulcers in Europe but not in United States).	48, 49	A
Statins		Single study showing decreased occurrence of ulcers.	50	A
Local management of ulcers		Wound-healing techniques, topical antibiotics, soaking, occlusion, débridement. Systemic antibiotics as necessary. Adequate analgesia (including narcotics if necessary).		
Surgical procedures				
Radical microarteriolytic, digital sympathectomy		Division of adventitia of digital arteries; sometimes termed <i>digital sympathectomy</i> . Useful treatment for individual critically ischemic digits.	51	B
Botulinum toxin A (Botox) "sympathectomy"		Small studies promising but clinical trials needed.	52	C
Débridement, amputation		Autoamputation is best to allow maximum preservation of healthy tissue. Surgery should be conservative and reserved for infection or intractable pain.		

**Findings of studies include this type of evidence:*
Level A: Randomized Controlled Clinical Trial, cohort study.
Level B: Retrospective Cohort, Exploratory Cohort, Outcomes Research, case-control study; or extrapolations from level A studies.
Level C: Case-series study or extrapolations from level B studies.
Level D: Expert opinion without explicit critical appraisal; or based on physiology, bench research, or first principles.
5-HT, 5-hydroxytryptamine.

although it does not speed ulcer healing.^{48,49} Bosentan (125 mg twice a day) has been approved for the prevention of digital ulcers in Europe but not in the United States. The high cost of this agent may limit clinical use. Statins display pleiotropic effects on endothelial function that may potentially retard vascular injury. A recent study using atorvastatin 40 mg daily showed a decreased frequency of new digital ulcers in scleroderma patients treated with the drug.⁵⁰

Ulcers located over bony prominences, such as the phalangeal joints and elbows, are thought to be caused by repetitive microtrauma and the difficulty in healing to be due to atrophic, avascular tissue overlying the joints. Management of both these ulcers and digital ulcers relies on wound-healing techniques, with soaking, application of topical antibiotic or débriding agents, and occlusion. Systemic antibiotics may be necessary. Adequate analgesia, even use of narcotics, may be necessary because severe pain leads to further vasospasm. Healing often takes a long time and patience is necessary. Surgical treatments that are gaining popularity include radical microarteriolytic (digital sympathectomy) and microvascularization in some patients with involvement of vessels other than digital ones.⁵¹ Endoscopic thoracic sympathectomy is being used in Japan, and botulinum toxin type A⁵² is being used by some hand plastic surgeons instead of digital sympathectomy.

Musculoskeletal complications

Most patients with SSc describe some musculoskeletal symptoms. Arthralgia, stiffness, and carpal tunnel syndrome are common early in the disease. Frank arthritis is uncommon and points toward an overlap syndrome. However, if there is significant synovitis that is not easily controlled, then treatment with hydroxychloroquine, methotrexate, or even anti-tumor necrosis factor may be effective.⁵³ Tendon friction rubs, noninflammatory fibrotic involvement of the tendons, are palpated primarily on the palms, wrists, and lower legs. They are associated with a poor prognosis primarily because they are most often seen in early diffuse scleroderma. They can thus be a clue to the diagnosis of scleroderma and diffuse scleroderma. The consequences of joint and skin involvement are contractures. In diffuse scleroderma these contractures can be very severe in the hands and wrists as well as in the proximal joints. An aggressive hands-on stretching exercise program should be an integral part of treatment for all patients newly diagnosed with diffuse scleroderma. It is very important to try to prevent the development of contractures, because once they are fixed they are extremely difficult to reverse even when the skin improves. Physical and occupational therapists must play an integral role in the management of scleroderma patients. Stretching exercises as opposed to strengthening exercises or

splinting seem to be the most effective and best tolerated and should be the mainstay of a home program as well. Even patients with limited scleroderma who have severe puffiness and tightness of the hands can benefit from a hand exercise program. Antiinflammatory agents and low-dose corticosteroids (5 to 10 mg prednisone/day) can be tried, particularly if there is joint or tendon inflammation. More important, however, is the control of pain. If there is severe pain with motion, the patient will not be able to perform the exercises adequately, and contractures will be worse. Often the pain is severe enough to require even low doses of long-acting narcotics. Most important is to keep patients comfortable to keep them moving.

Muscle involvement can be both a typical inflammatory myositis akin to polymyositis and a blander fibrotic myopathy. Both can be associated with an elevation in the creatine phosphokinase level, but inflammatory findings on electromyography, magnetic resonance imaging, and biopsy should guide the treatment. If the muscle weakness is mild, then methotrexate and/or azathioprine with low-dose prednisone may be enough to treat the inflammatory myositis. If high-dose prednisone is necessary, careful observation of blood pressure is necessary to ensure that renal crisis does not develop. There is no evidence that ACE inhibitors aid in preventing renal crisis, so they should not be used unless the patient develops hypertension. At that time, very close monitoring of the blood pressure and renal function is necessary. Patients with a bland myopathy may respond to low-dose prednisone but more important is muscle strengthening. Patients with mild proximal weakness can develop shoulder contractures, so stretching exercises as well as strengthening exercises should be done.

Skin disease

Skin sclerosis is present in patients with almost all forms of SSc except in some patients with very early disease and those with the rare subtype designated *systemic sclerosis sine scleroderma* in whom vascular and visceral manifestations occur in the absence of skin involvement. Treatment of the disease is rarely dictated by its cutaneous manifestations, however. Visceral involvement is far more important in terms of morbidity and mortality. Nevertheless, skin discomfort, pruritus, burning, and actual pain can be very debilitating in patients with early diffuse scleroderma. Systemic antihistamine therapy can provide some relief for intractable itching; pregabalin seems to be helpful for the prickly, burning pain that may be caused by entrapment of the cutaneous sympathetic nerves by the thickened skin; and narcotic analgesia may be necessary for the painful skin. Use of topical agents has not been associated with clinical softening, but emollients, moisturizers, and topical anesthetics may give some patients temporary relief.

It is not uncommon for patients with severe skin sclerosis to experience stabilization and even softening of the skin with time, especially by 5 years from diagnosis. This improvement in skin thickening, whether it is due to the natural history or the effect of medication, is also associated with improved survival.⁵⁴

Another frequent cutaneous manifestation of scleroderma is the development of cutaneous dilated loops of small blood vessels (telangiectasia). It should be noted that telangiectasia, although it occurs especially in patients with limited cutaneous SSc (sometimes termed *CREST syndrome* [calcinosis, Raynaud phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia])—also is frequently present in patients with late-stage diffuse cutaneous SSc. Indeed these patients may become more florid in the plateau phase of diffuse cutaneous SSc, even when the skin sclerosis diminishes. These lesions are often distressful to patients cosmetically but also because of concern that they indicate the disease is progressing. Patients should be reassured that they have no relationship to disease activity. Hemorrhage from mucosal telangiectasia is also becoming increasingly recognized as a clinical problem and may require local therapy if it is recurrent. Cosmetic camouflage techniques can be very effective for masking facial telangiectasia, and appropriate advice should be offered to all patients who might benefit. Recently pulsed dye laser therapy has also been used with some success.

In addition to skin thickening, other cutaneous manifestations include calcinotic nodules, especially in limited scleroderma. No medical therapy has been shown to be effective. Local pain, progression of contractures, and functional impairment occur and may contribute to ulcer formation. Surgical removal may be beneficial, although often the calcinosis is too diffuse within the tissue to debulk easily. The pathogenesis of calcinosis is not known and has not been studied very well. A recent study found that the protein expression of osteonectin and matrix carboxyglutamic acid was increased in SSc patients compared with controls and particularly in patients with calcinosis.⁵⁵ These proteins are known to play a role in some types of calcification processes in other diseases, so perhaps further studies will lead to a better understanding of this process. Although warfarin, colchicine,

probenecid, bisphosphonates, diltiazem, minocycline, aluminum hydroxide, salicylate, surgical extirpation, and carbon dioxide laser therapies have been used, no treatment has convincingly prevented or reduced calcinosis.⁵⁶ Tumor necrosis factor- α inhibition was reported to improve calcinosis symptoms in patients with juvenile dermatomyositis, so perhaps it may be helpful in some cases.

Macrovascular disease

In addition to the classic involvement of the renal and pulmonary arteries, macrovascular disease has been reported to be increased in SSc. Involvement of the large arteries in the extremities can lead to ischemia. Increased aortic arterial stiffness, impaired endothelium-dependent vasodilatation, and increased coronary artery calcification have been seen in scleroderma, but in one study investigators could not find increased signs of atherosclerosis or premature myocardial infarctions.⁵⁷ Most survival studies do not show increased coronary artery-related deaths in scleroderma, although cardiopulmonary deaths are very common. One study found that acute myocardial infarctions occurred in only 1% of 1000 hospitalizations of scleroderma patients and was thus quite unusual.⁵⁸

Gastrointestinal complications

Involvement of the gastrointestinal tract is extremely common in scleroderma (Table 144.3). Abnormalities have been demonstrated throughout its length, although esophageal involvement is the most frequently, occurring in up to 80% of patients. Simple measures such as elevating the head of the bed and not eating for several hours before bed are important and useful adjuncts to more sophisticated treatments. Clinical benefit is obtained from acid-suppressive therapies and proton pump inhibitors are dramatically effective, so that use of these as first-line treatment often is justified. High doses may be needed to control severe esophagitis. Additional benefit can be obtained from adding a motility drug such as metoclopramide, although it has many adverse effects. Unfortunately, cisapride and a related motility drug, domperidone, which have fewer adverse effects, are unavailable in the United States. Erythromycin also has some promotility effects, which are most effective in the stomach.

Small intestinal hypomotility with pseudo-obstruction and bacterial overgrowth has been shown to occur frequently in SSc. Bloating, nausea, vomiting, diarrhea, abdominal distention, and malabsorption may occur and may be devastating, because there is no treatment that can reverse this process. Promotility agents including metoclopramide, domperidone, and erythromycin can be helpful, but as noted earlier they often have adverse effects, and the associated cardiac toxicity has led the FDA to withdraw approval for several agents. Broad-spectrum antibiotics, including metronidazole, ciprofloxacin, tetracycline, and amoxicillin in varying dosages, are helpful in treating bacterial overgrowth and can be dramatically effective in some cases. Sometimes intermittent courses of a single agent are effective, but refractory cases may require rotation of antibiotics. There is no one approach that can be used for all patients. Different regimens of antibiotics must be tried. Although a hydrogen breath test may confirm bacterial overgrowth, an empiric trial of antibiotics should be initiated in symptomatic patients even without this test. In severe cases with malnutrition, octreotide (subcutaneous octreotide 0.1 mg twice daily or intramuscular octreotide long-acting release 20 mg/mo) has been used effectively.⁵⁹ Consumption of frequent small meals, use of high-protein supplements, and in refractory cases total parenteral nutrition may be necessary. Gastric or jejunal feeding tubes should not be used, even in patients with severe esophageal problems, because of the poor motility throughout the intestinal track in scleroderma. Gastroparesis is present in up to 50% of scleroderma patients and contributes to the esophageal and small bowel symptoms in these patients.

Gastric antral venous ectasia has a characteristic appearance on endoscopy that has led to the name *watermelon stomach*. It manifests as iron-deficiency anemia due to recurrent or chronic gastrointestinal bleeding, which is often silent and entirely asymptomatic until severe anemia develops. A recent study found this complication not only in patients with long-standing limited scleroderma but also in patients with early severe diffuse scleroderma associated with the anti-RNA polymerase III antibody.⁶⁰ It is an important diagnosis because the condition is potentially life-threatening and also because it is amenable to treatment using laser photocoagulation. Such intervention is warranted because chronic hemorrhage from these and other telangiectatic lesions is a significant cause of iron deficiency in SSc.

Anal involvement is also common but is underdiagnosed. Incontinence, often described as diarrhea by patients, is the most common complaint. It is important to inquire specifically about anorectal dysfunction so that

TABLE 144.3
Gastrointestinal tract disorders in systemic sclerosis

Site	Disorder	Symptom	Investigation	Treatment
Mouth	Tight skin Dental caries Sicca syndrome	Cosmetic Toothache Dry mouth	None Dental radiograph Salivary gland biopsy	Facial exercises Dental treatment Artificial saliva
Esophagus	Dysmotility/esophageal spasm Reflux esophagitis Stricture	Dysphagia Heartburn Dysphagia	Barium swallow Esophageal scintigraphy Manometry, endoscopy	Proton pump inhibitors Minimize NSAID and calcium channel blocker use Elevate head of bed, avoid late meals
Stomach	Gastric paresis NSAID-related ulcer Gastric antral vascular ectasia or watermelon stomach	Anorexia Nausea, early satiety Severe anemia, silent blood loss	Scintigraphy Endoscopy, barium meal Endoscopy	Proton pump inhibitors Metoclopramide, domperidone Laser coagulation
Small bowel	Hypomotility Stasis Bacterial overgrowth NSAID enteropathy Pseudo-obstruction Pneumatosis intestinalis	Weight loss Postprandial bloating Malabsorption Steatorrhea Abdominal pain Distention Diarrhea with blood, benign pneumoperitoneum	Barium follow-through ¹⁴ C glycocholate or hydrogen Breath test Jejunal aspiration Fecal microscopy Plain abdominal radiography Plain abdominal radiography	Rotational antibiotics, metronidazole, ciprofloxacin, rifaximin Domperidone, metoclopramide Octreotide (low dose) Oral nutritional supplements Parenteral nutritional support Conservative management
Large bowel	Hypomotility Colonic pseudodiverticula Pseudo-obstruction	Alternating constipation and diarrhea Rare perforation Abdominal pain, distention	Barium enema/CT of abdomen Barium enema/CT of abdomen Plain abdominal radiography	Dietary manipulation, stool expanders for constipation, loperamide for diarrhea (Resection as a last resort) Conservative management
Anus	Sphincter involvement	Fecal incontinence	Rectal manometry	Kegel exercises, protective measures, sacral nerve stimulation

CT, computed tomography; NSAID, nonsteroidal antiinflammatory drug.

patients can be offered clear advice to help them cope with this distressing manifestation.

Barrett metaplasia of the lower esophageal mucosa is quite common in SSc patients, although the optimal frequency of surveillance and treatment of minor abnormalities is unclear. Reports suggest that metaplasia can improve and that malignant transformation is less frequent than in patients without SSc.

Cardiac disease

Cardiac involvement in scleroderma is common, as demonstrated by a variety of noninvasive tests and autopsy studies, but its contribution to patient outcomes is unclear. Severe cardiomyopathies are unusual but can be associated with renal crisis and systemic myositis. Other cardiac features including pericardial effusions, arrhythmias, and diastolic dysfunction are quite common.

Treatment of cardiac manifestations currently parallels the management of similar clinical events occurring outside the context of SSc. Thus antiarrhythmic agents are used to treat hemodynamically significant dysrhythmias and pacemaker insertion is considered when there is evidence of significant conduction abnormalities. Conduction defects are the most frequent electrophysiologic disturbances in SSc, and these may be associated with reentrant tachyarrhythmias. Some cases have been reported in which reentrant monomorphic ventricular tachycardia in SSc patients responded to local ablative therapy. At this point, optimal treatment of this type of diastolic dysfunction has not been clarified even in nonscleroderma patients.

Levels of markers of myocardial damage such as troponin T and N-terminal pro-brain natriuretic peptide, which are common markers for both left- and right-sided heart failure, are often elevated in SSc and may be helpful in monitoring response to treatment for cardiac disease. There is no evidence that any immunosuppressive or vasodilator has had any specific effect in scleroderma heart disease.

Renal scleroderma

The most important renal complication in SSc is scleroderma renal crisis (Fig. 144.2). Several studies have documented that corticosteroid use (more than 15 mg prednisone per day or equivalent) may predispose to the development of scleroderma renal crisis.⁶¹ Patients at increased risk, particularly

Fig. 144.2 Management of scleroderma renal crisis requires careful evaluation, prompt diagnosis, and aggressive treatment with ACE-inhibitors. ACE, angiotensin-converting enzyme; BP, blood pressure; MAHA, microangiopathy hemolytic anemia; SSc, systemic sclerosis.

those with early diffuse cutaneous disease, should be educated to monitor their blood pressure regularly. New-onset hypertension, often with marked elevation of pressure, and retinopathy and other signs of end-organ damage, including blood and protein in the urine, are indications of a life-threatening illness. Widespread early use of ACE inhibitors has clearly improved survival rate,⁶² but the overall prognosis of scleroderma renal crisis still is not adequate. Thirty percent of patients still progress to renal replacement

therapy. It is nevertheless a significant mark of progress that renal crisis is no longer the most frequent cause of scleroderma-associated death.⁶³

Hypertension should be treated with ACE inhibitors. The use of shorter-acting captopril allows more flexibility in adjusting the dosage, but any ACE inhibitor is effective. Although angiotensin receptor blockers and renin inhibitors should be effective in treating scleroderma renal crisis, there is little information as to their effectiveness compared with ACE inhibitors. Renal function often continues to deteriorate even after blood pressure is adequately controlled, but the ACE inhibitor must be continued. If maximum ACE inhibition has not controlled blood pressure, the use of calcium channel blockers, hydralazine, or clonidine may be necessary.⁶⁴ There is controversy over whether prophylactic use of ACE inhibitors prevents renal crisis. However, two recent studies examining the British and French experience with renal crisis in large scleroderma populations have shown a worse outcome in patients who, for whatever reason, used ACE inhibitors before renal crisis occurred.^{65,66} Additionally, a prospective observational study confirmed that prior treatment with ACE inhibitors before the onset of renal crisis was associated with increased morbidity and mortality.⁶⁷ The reason for a worse outcome may be that the low dosage of ACE inhibitors does not prevent the development of renal crisis and instead blunts the effects of the acute hyperreninemia, thus masking the onset of renal crisis and causing a more chronic, less reversible process. Thus, if an ACE inhibitor is being used, a high-risk patient still needs to be followed very closely.

An audit of the United Network for Organ Sharing database in North America confirmed the feasibility and acceptable long-term outcome of renal transplantation in patients with SSc.⁶⁸ Considerable recovery in renal function often occurs after an acute crisis, and improvement can continue for up to 2 years, which frequently allows dialysis to be discontinued. Therefore decisions regarding renal transplantation should not be made before this time.

SUMMARY

Although SSc is an uncommon disease, it is an important one because it has the highest mortality of any of the rheumatic disorders. Also, much can be learned from it, because it is a paradigm for other more common medical conditions in which immunologically triggered fibrosis occurs, such as liver cirrhosis and idiopathic pulmonary fibrosis. All patients with scleroderma-spectrum disorders should be assessed by physicians familiar with these conditions. In this way the diagnosis is confirmed, patients can be educated about the disease, and follow-up and treatment can be tailored according to stage, subset, and activity. Further advances in management will require interventional studies to confirm the efficacy of current treatments and test novel agents. Management of life-threatening complications should be proactive, with screening of patients at risk and commencement of therapy at the earliest opportunity. Importantly, there have been real advances in the management of the major and most deadly complications. ACE inhibitors appear to have substantially improved survival of renal scleroderma crisis. There is evidence that cyclophosphamide is effective in scleroderma-associated pulmonary disease, and there are now many therapeutic agents approved for use in pulmonary hypertension, which makes even this previous deadly complication treatable. Improved management of Raynaud phenomenon with calcium channel blockers, treatment of reflux with proton pump inhibitors, and aggressive physical therapy have all improved the morbidity of scleroderma.

Survival studies strongly suggest that outcomes for scleroderma patients have improved significantly over the past 25 years, and scleroderma should now be considered treatable, if not curable. More therapeutic agents are being studied in scleroderma than ever before, which brings more hope that they will lead to even better management and effective treatment for all aspects of this difficult disease.

Pulmonary management of systemic sclerosis

■ CHRISTOPHER P. DENTON ■ VOON H. ONG

- Significant progress has been made over the past decade in the assessment and management of pulmonary complications of systemic sclerosis, particularly interstitial lung disease and pulmonary arterial hypertension (PAH).
- High-resolution computed tomography and lung function tests are critical in detection and treatment of interstitial lung disease and also in prediction of outcome with treatment.
- Patients are most at risk of rapid decline in lung fibrosis in early-stage scleroderma, and treatment with cyclophosphamide may lead to stabilization of disease.
- With a goal-directed approach and current PAH-specific therapies, survival has improved, although the extent to which contributory processes such as coexisting lung disease may operate justifies careful consideration, and use of a screening algorithm for those at risk may improve early detection and treatment.

INTRODUCTION

Pulmonary complications of systemic sclerosis (SSc) are the single largest cause of disease-related mortality in a condition that has the highest death rate of any of the autoimmune rheumatic diseases. There has been significant progress in the area of management—in particular, in the assessment and treatment of both interstitial lung fibrosis and pulmonary arterial hypertension (PAH), the two most important pulmonary manifestations of SSc.

SPECTRUM OF PULMONARY INVOLVEMENT IN SYSTEMIC SCLEROSIS

There are many ways in which SSc can affect the lungs, although the two most important complications are PAH and interstitial fibrosis, shown histologically in [Fig. 145.1](#). This includes involvement of the chest wall skin and underlying connective tissue that may directly restrict respiratory excursion, muscle involvement with inflammation, and fibrosis that impairs ventilation of the lungs. Pleural disease can occur with pleural effusions, although this is less common than in other inflammatory rheumatic diseases and may be a clinical indication of an overlap syndrome.

Interstitial fibrosis is common in SSc but of variable severity and in some cases may not be clinically significant. Identification of more severe cases and prediction of the likelihood of future progression are cornerstones of the management of SSc-associated pulmonary fibrosis. Most often, lung fibrosis has a pattern of nonspecific interstitial pneumonia (NSIP) on histologic examination and high-resolution computed tomography (HRCT), although other forms may occur, especially usual interstitial pneumonia (UIP) and organizing pneumonia, that can later progress to NSIP.

Pulmonary vascular disease represents another frequent and important manifestation. Postcapillary PAH is the most common form of the disease, and this is a complication that has benefited from major therapeutic advances over the past decade. However, other forms of pulmonary hypertension occur, including cases due to lung fibrosis and hypoxia (group 3) and cases associated with cardiac involvement, notably diastolic dysfunction (group 2). Another important form of PAH is classified in the 1' group, pulmonary venoocclusive disease (PVOD).

Recent studies also reported cases of aspiration pneumonia and lung malignancy in patients with SSc and interstitial lung fibrosis. Cardiac complications including cardiac failure and pulmonary edema are also important.

Dyspnea in systemic sclerosis

All patients with scleroderma should be regularly evaluated to identify the presence of symptoms that could reflect significant pulmonary disease. Breathlessness is very frequent in SSc and may have multiple causes ([Fig. 145.2](#)). Careful questioning and assessment for associated factors including chest wall myopathy, deconditioning, and cardiac disease are critical to differentiate the underlying mechanisms. Formal assessment of dyspnea remains challenging, and several scoring systems have been developed to aid in assessment of dyspnea.¹

PULMONARY FIBROSIS

Interstitial lung disease (ILD) is one of the most prevalent and important complications of SSc. Although moderate to severe lung fibrosis is identified in around 25% of SSc cases, overall there are important differences between subsets of the disease. Thus approximately one third of patients with diffuse cutaneous scleroderma (dcSSc) compared with around one sixth of patients with limited cutaneous scleroderma (lcSSc) are affected by significant fibrosis.² Moreover, the frequency of milder disease is high, so that more than half of SSc patients overall have some evidence of interstitial fibrosis. The rate is even higher within some serologically defined subgroups, such as patients who test positive for anti-topoisomerase I autoantibody.³

The main differential diagnosis is between the various forms of diffuse ILD and other important pulmonary complications of SSc, such as PAH. The two complications may occur concurrently, although in the majority of cases there is a clear predominance of one process. Nevertheless, the coexistence of pulmonary vascular disease may have an important impact on outcome.

Investigations

Plain radiography

Although the current preliminary classification criteria for SSc call for chest radiography as a means to determine the presence of lung fibrosis, this is recognized to be an insensitive tool to detect mild ILD.⁴ In general, plain radiography is useful as a screening tool for other pulmonary complications and may provide important additional information but cannot be relied on as a method for defining or excluding significant lung fibrosis. Subtle volume loss may occur in early-stage disease, but this may be apparent only on HRCT scans, and even with established pulmonary disease, the chest radiographic findings may be essentially normal.

High-resolution computed tomography

The cornerstone of detection of lung fibrosis in SSc is HRCT.⁵ HRCT is important because it provides a very sensitive tool for detection of disease and permits the pattern and extent of disease to be assessed. Although there is no consensus on whether to perform HRCT as a screening test in all cases of SSc, in practice most clinicians target only symptomatic patients or those with declining pulmonary function test (PFT) results. Initial assessment should include prone images so that minor interstitial changes of dependency can be excluded, although this may be less of an issue with modern multichannel scanners that require only a short examination time. Resolution of scanners is improving, and radiation exposure is being reduced. Nevertheless, the value of serial CT assessment over and above longitudinal

Fig. 145.1 Histopathologic features of systemic sclerosis (SSc)-associated lung disease. (a) Pulmonary arterial hypertension (PAH). Autopsy specimen from a patient with limited cutaneous SSc with advanced isolated PAH showing thickened pulmonary arterial wall and endoluminal proliferative lesions (plexiform lesion), in this case treated with combination targeted therapy including prostanoid, phosphodiesterase-5 inhibitor, and endothelin receptor antagonist. (b) Lung fibrosis in SSc. Nonspecific interstitial pneumonia pattern with preservation of architecture, homogeneous pattern of fibrosis, and absence of fibroblastic foci. This patient was considered to have stable lung fibrosis over several years of follow-up but died of gastrointestinal disease.

measurement of lung function together with baseline HRCT is not established. Examples of HRCT appearance are shown in Fig. 145.3 contrasting mild and extensive disease.

The pattern as well as extent of ILD may be determined by HRCT. This permits identification of an NSIP or UIP pattern of disease, and studies have shown that in scleroderma the HRCT definition correlates well with histologic pattern.⁶ Experienced assessors may identify features that are suggestive of inflammatory activity within lung tissue (alveolitis), but this is very challenging because fine interstitial fibrosis may give rise to an almost identical appearance. The presence of associated volume loss, traction bronchiectasis, and other features may be used in interpreting HRCT findings. In some cases there is clear evidence of reticular change that can reflect only established disease, but in others more diffuse ground-glass attenuation is present, and this more often represents fine fibrosis rather than true inflammation (Fig. 145.4). The development of a simple staging system has been an important and useful step forward in clinical management.⁷ In this algorithm a rapid assessment by HRCT is integrated with basic PFT variables to

determine whether there is mild or extensive disease and stratify the likelihood of progression. More formal scoring of the extent of disease has been used in validating studies, including a threshold analysis. These studies point to a higher risk of progression when more than 20% to 25% of lung volume is affected by fibrosis. However, scoring systems are observer dependent and applicable only to clinical research studies at present. There have been other attempts to use image analysis to determine extent of disease, but such systems have limitations and at present are not considered superior to an experienced observer-based scoring system.

Modern scanning and poststudy reconstruction can be invaluable in defining the precise extent of fibrosis, and such methods may ultimately be important in assessing disease progress and treatment response. Reconstructed images in typical cases of mild and extensive SSc-associated lung fibrosis are provided in Figs. 145.5 and 145.6, respectively.

Pulmonary function testing

Other tests that are valuable include PFTs, which form the mainstay of longitudinal assessment. For use in routine clinical practice the single most important assessment is the forced vital capacity (FVC), expressed as a percentage of the predicted value for age, weight, and gender.⁸ This has been determined to be the most robust assessment in stratifying cases of SSc-associated pulmonary fibrosis for treatment and also in assessing patients at follow-up. It has been validated as an outcome measure in several studies of ILD.

The diffusion capacity of the lung for carbon dioxide (DLCO) is a sensitive marker but also reflects the pulmonary vasculopathy that may coexist with ILD. Measures of total lung capacity are less dependent on exertional effort than FVC but are more demanding to ascertain and appear to add little value in assessment.⁹

Lung biopsy

A lung biopsy can be undertaken using a variety of different methods. These include the use of video-assisted thoracoscopic sampling, which probably is the most widely used method. Other approaches include open lung biopsy, which may be appropriate if larger samples are needed but is much more invasive. Transbronchial biopsy has specific utility in some situations, such as when malignancy or certain infective processes are suspected, but is of very limited value for the assessment of interstitial fibrosis owing to the limited sampling that is possible. It should be noted that the histologic pattern of biopsy specimens in SSc-related pulmonary fibrosis has not been demonstrated to be associated with outcome, unlike in idiopathic lung fibrosis, and this makes biopsy of less importance in uncomplicated typical cases.¹⁰ It remains an important diagnostic tool for cases that are atypical either clinically or on HRCT because there may be major management implications if there is diagnostic uncertainty. There is an excellent correlation between NSIP and UIP designations by HRCT and lung biopsy.⁵ Together these factors mean that biopsy is much less important than in the past, and it is not regarded as a routine test for management of SSc-associated lung disease. An exception is when malignancy is suspected or when there is the possibility of an alternative diffuse lung process, especially if high-dose corticosteroid treatment is considered. Use of high-dose corticosteroids in SSc can be harmful owing to increased risk of renal crisis in SSc, especially in the diffuse subset.

Serologic assessment

For baseline risk stratification and longitudinal assessment of interstitial lung fibrosis in SSc it would be enormously helpful to have reliable serum markers that reflect the extent or activity of fibrosis. In SSc there are a number of potential biomarkers, which can be separated into those that may reflect pathologic processes at multiple sites but have been shown to associate with lung fibrosis and those that have the potential to be more specific for pulmonary disease. Examples of general markers are markers of fibrosis such as CCN2¹¹ and chemokines such as CCL2.^{12,13} As well as being markers of disease, these may also be mediators of pathogenesis and future targets of therapy.¹⁴ In contrast, other more specific markers arise from lung tissue. Glycoproteins secreted by type II pneumocytes such as Krebs von den Lungen-6 (KL-6) and surfactant protein D have been shown to be present at increased levels in the sera of SSc patients with lung fibrosis when the alveolar epithelium is damaged, and by analogy, similar findings have been reported in cases of idiopathic pulmonary fibrosis.¹⁵ It is possible that the levels reflect the degree of damage or repair occurring in diseased lung tissue. It has been suggested that serum levels of these biomarkers correlate with the extent of fibrosis on HRCT and that higher baseline serum KL-6 levels are associated with decline in FVC. Therefore measurement of KL-6 may help to diagnose and monitor progression of lung fibrosis, and this is an important area for future clinical research.

Fig. 145.2 Schematic representation of the multiple interacting mechanisms that may underlie the common symptom of dyspnea in systemic sclerosis (SSc). Musculoskeletal deconditioning is probably the most common basis for this symptom and may respond to cardiorespiratory and physical rehabilitation programs. However, major lung or heart disease must be excluded or investigated before simpler strategies are employed. ARDS, acute respiratory distress syndrome; DAD, diffuse alveolar damage; GAVE, gastric antral vascular ectasia; GI, gastrointestinal; NSIP, nonspecific interstitial pneumonia; PAH, pulmonary arterial hypertension; SLE, systemic lupus erythematosus; UIP, usual interstitial pneumonia.

Fig. 145.3 Determining the extent of lung fibrosis in systemic sclerosis (SSc)—a critical role for high-resolution computed tomography (HRCT). (a) Minimal lung fibrosis in early SSc. Initial staging HRCT should be performed with the patient prone so that minor effects of blood distribution or fluid are excluded as explanations for minor basal lung disease. This scan shows trivial disease that would not be associated with chest radiographic findings in the lung fields. (b) Extensive lung fibrosis. This scan shows typical features of extensive lung fibrosis in SSc that will require active treatment because there is a high risk of future decline. In these scans more than 75% of the lung field is involved.

Diethylenetriamine pentaacetic acid lung scanning

Rather than explore the level of soluble glycoproteins derived from pulmonary epithelial cells such as KL-6, a more direct way of exploring epithelial injury in SSc-associated pulmonary fibrosis is measurement of the clearance rate of an inhaled nebulized suspension of diethylenetriamine pentaacetic acid (DTPA). The DTPA is deposited within the alveolar tissue of the lung, and the rate of clearance into the blood and away from the lungs reflects the degree of epithelial layer permeability. A growing body of data point toward DTPA clearance rate as a marker of the likelihood of progression of pulmonary fibrosis in SSc. The test is of limited value in individuals who smoke owing to the known effects of tobacco smoke, which lead to accelerated clearance. A calculated half-life can be used to determine the presence of accelerated clearance, and current studies suggest that a half-life of less than 45 minutes is abnormal. Published data indicate that DTPA lung

studies have additional value over HRCT and that results are linked to disease severity and predictive of disease progression.¹⁶

Bronchoalveolar lavage

In most cases of pulmonary fibrosis in patients with SSc bronchoalveolar lavage (BAL) adds little diagnostic or prognostic information beyond what can be derived from PFTs and HRCT. This is contrary to earlier opinion, which suggested that BAL fluid pleocytosis correlated with alveolar inflammation, considered to be a driving mechanism in pulmonary fibrosis in these patients. Recent studies have shown that BAL neutrophilia or eosinophilia is not predictive of response to immunosuppressive treatment (e.g., cyclophosphamide). In addition, as with HRCT, it has been shown that BAL changes are not specific. In fact, there may be inflammatory changes in all contexts in SSc-associated lung fibrosis.¹⁷

Fig. 145.4 Pattern of interstitial change in systemic sclerosis (SSc)—associated lung disease—utility of high-resolution computed tomography (HRCT). (a) Ground-glass appearance. Amorphous shadowing is present throughout the lung parenchyma in this representative slice of HRCT in a patient with early diffuse SSc. It can be difficult to differentiate inflammation from fine fibrosis, and so this appearance cannot be regarded as synonymous with alveolitis. In later established disease there may be traction bronchiectasis and other features that allow fibrosis to be determined with confidence. Extent of involvement appears to be more important than pattern of abnormality in predicting likelihood of progression. Pattern of change does not predict responsiveness to immunosuppression. (b) Reticular honeycomb appearance. Established fibrosis is associated with a typical coarse reticular pattern of abnormality. Biopsy studies confirmed that there may be inflammatory foci within this tissue, and so some reversibility is possible. As with other appearances in SSc, lung fibrosis extent is more important than pattern of abnormality in predicting outcome.

Fig. 145.5 High-resolution computed tomography can confirm the extent of fibrosis in systemic sclerosis. (a and b) Coronal reconstructions showing basal disease with mild extent and predominantly basolateral distribution. (c) Representative cross-sectional image.

Fig. 145.6 Extensive lung disease in systemic sclerosis. (a and b) Coronal reconstructions showing extensive ground-glass opacification exceeding 25%. (c) Representative cross-sectional image showing subpleural reticulation in the lung bases with dilatation of the esophagus.

BOX 145.1 CLINICAL ASSOCIATIONS WITH SIGNIFICANT LUNG FIBROSIS IN SYSTEMIC SCLEROSIS

- Diffuse pattern of skin involvement
- Autoantibody profile
 - Anti-scleroderma-70 (anti-topoisomerase I autoantibody)
 - Anti-Th/To
 - Anti-PM-Scl
 - Anti-U11/U12
- Less than 3 years' disease duration
- Severe gastroesophageal reflux
- Rapid clearance of diethylenetriamine pentaacetic acid
- High Krebs von den Lungen 6 level

In certain cases, however, BAL is still extremely useful. It can be used to determine the likely presence of infection such as tuberculosis by direct staining or culture as well as by polymerase chain reaction analysis. It may point toward an alternative pathologic process to SSc, such as lymphocytosis in sarcoid. In addition, it has great utility as a research tool.

Screening

All patients with SSc should undergo regular screening for ILD. Recent studies suggest that with annual PFTs and HRCT performed at baseline or if there is suspicion of lung fibrosis during follow-up there is now a much better and more complete ascertainment of moderate to severe lung fibrosis in SSc. Thus there has been a significant improvement in the past decade at the authors' own center. Approximately 34% of patients with diffuse cutaneous SSc (dcSSc) and 16% with limited cutaneous SSc (lcSSc) developed lung fibrosis by 5 years, and there is a steady rise to 45% and 21% for each disease subset, respectively, at 10 years. Because in the authors' cohort the frequency of lcSSc is approximately twice that of dcSSc, the absolute numbers of patients affected with clinically significant lung fibrosis are approximately equal for each major subset despite the apparent relative frequency of this complication among patients with dcSSc. Currently, annual PFTs are recommended as screening tests for lung disease in SSc.

Clinical high-risk associations

Although it is now clear that lung fibrosis is very common in SSc and probably affects up to half of patients with a confirmed diagnosis of SSc, the number with major, potentially clinically significant ILD is much smaller, probably about 25% of cases overall. There are important clinical and investigational features that point toward an increased risk of lung fibrosis, and some of these characteristics are present at diagnosis. This offers the real possibility of risk stratification. Thus patients who have anti-topoisomerase I antinuclear autoantibodies (also known as *anti-scleroderma-70* or *anti-Scl-70* antibodies) have been shown in many independent studies in a variety of geographically and ethnically diverse patient populations to have a significantly increased frequency of lung fibrosis. In some studies,¹⁸ this approaches 66% of cases. There is also an association with other reactivities that are less common, such as those against Th/To,¹⁹ PM-Scl,²⁰ and U11/U12. Conversely, anticentromere reactivity or anti-RNA polymerase-specific antibodies have been found to be somewhat protective from lung fibrosis in prevalence studies, although they are associated with other complications of SSc that may lead to breathlessness, namely, PAH and scleroderma renal crisis. These are important simple clinical indicators. It has been demonstrated that overall diffuse skin involvement is more likely to be associated with lung fibrosis, but the extent of skin disease (as assessed by the modified Rodnan skin score) does not appear to predict extent or severity of lung fibrosis. Another association is early-stage disease. Data from the authors' cohort indicate that over half of those with significant lung fibrosis developed it within the first 3 years of disease onset. Lung fibrosis is also linked with a decline in FVC within the first 4 to 6 years of disease. Thus there is an important population of dcSSc patients who have significant lung fibrosis at diagnosis, and indeed it may on occasion be the presenting feature of the disease. The key features associated with lung fibrosis that are useful clinical pointers are summarized in Box 145.1.

Differential diagnosis

Diagnosis of SSc-associated pulmonary fibrosis is made using a composite of the tests outlined earlier, but HRCT is the most sensitive test for detecting

Fig. 145.7 Lung cancer may occur in association with interstitial lung disease in systemic sclerosis. Supine high-resolution computed tomographic scan demonstrates the typical changes of nonspecific interstitial pneumonia with widespread fine subpleural reticulation with some traction bronchiectasis. A spiculated irregular nodule is detected in the right lower base. In this patient, positron emission tomography confirmed increased uptake over the lesion. Due to the proximity of the lesion to the chest wall and ribs, computed tomography-guided biopsy and a bronchoscopic approach were not deemed to be feasible. The patient underwent open lung biopsy, and the histologic analysis confirmed adenocarcinoma.

and determining the pattern and extent of lung fibrosis. This is supplemented by measurement of FVC. Other tests may be performed as necessary. The key to effective management is assessment and staging of lung fibrosis and exclusion or confirmation and delineation of other manifestations of SSc that may lead to dyspnea. It is important that in patients with known lung fibrosis who experience unexplained worsening of breathlessness, the possibility of lung cancer should be considered (Fig. 145.7). Although lung cancer is one of the most common malignancies reported in SSc, the absolute risk is probably low, and its association with severity of lung fibrosis and smoking remains unproven. Another important differential diagnosis is recurrent aspiration related to reflux disease (Fig. 145.8). Severe reflux may be linked to lung fibrosis, but further studies are needed to evaluate a possible causal relationship between the two diseases.²¹

Staging

A simple staging system has been developed recently that integrates lung function test results with HRCT appearance.⁷ This system, the UK-RSA staging method, was developed using a cohort of well-characterized SSc patients who had been followed over time and links lung function together with rapid evaluation of CT appearance. It depends on the strength of HRCT in assessing the extremes of disease—mild or extensive—together with an assessment of volume loss in intermediate cases that cannot easily be categorized by a rapid HRCT review. The FVC as a percentage of predicted value performs well in this context and was found to be more reliable for the purposes of staging than the DLCO. This may partly reflect the impact of coexistent pulmonary vascular disease on gas transfer measurement. An FVC above 70% predicted is associated with a better outcome in terms of progression-free survival. These data are integrated into the simple algorithm shown in Fig. 145.9. This works to the strength of both assessment tools. HRCT is very robust at lower and high levels of disease, and FVC is helpful in between. This method has been shown to perform well and is supported by outcome data. It is strongly recommended that it be used by rheumatologists in assessing and treating SSc-associated pulmonary fibrosis. It has not been applied formally to other forms of lung fibrosis, but similar strategies could be developed, validated, and used.⁷

Fig. 145.8 Severe esophageal dysmotility may predispose to recurrent aspiration in systemic sclerosis. This patient with upper midgut dysmotility had a persistent nocturnal cough. The erect chest radiograph shows right lower zone consolidation consistent with aspiration pneumonia. Optimization of antireflux treatment and prokinetics may help to prevent microaspiration, which may otherwise initiate or exacerbate lung fibrosis.

Fig. 145.9 This simple staging system for lung fibrosis in systemic sclerosis (SSc) is derived from analysis of data for a cohort of well-characterized SSc cases and links results of lung function tests and high-resolution computed tomography (HRCT) that are routinely used in disease assessment. Cases can be separated into mild or extensive, and patients with the former may be observed without treatment because they have a lower risk of future progression. Documented worsening should prompt initiation of therapy, currently with immunosuppressive drugs as outlined in the text. FVC, forced vital capacity. (From Goh NS, Desai SR, Veeraraghavan S, et al. *Interstitial lung disease in systemic sclerosis: a simple staging system*. *Am J Respir Crit Care Med* 2008;177:1248-54.)

Treatment

Although lung fibrosis is a major cause of SSc-related death, the treatment of lung fibrosis in SSc remains very inadequate. A fundamental management challenge is the fact that not all cases of SSc-associated pulmonary fibrosis will progress or even be clinically significant. This is a particular issue when HRCT is widely used for diagnosis, because there is a high frequency of detection of subclinical and trivial disease. The decision to treat therefore rests on whether the patient is clinically affected by the disease, whether it is progressive, and what other mitigating factors exist. The staging algorithm outlined earlier is invaluable in differentiating cases for which meticulous observation is appropriate from those that should be actively treated.

Active treatment currently centers on immunosuppressant therapy. In many centers, the mainstay of therapy for SSc-associated ILD has long been corticosteroids and/or cyclophosphamide, given orally or as an intermittent intravenous bolus. Some recently completed randomized controlled trials demonstrated a modest benefit for cyclophosphamide over placebo.²²⁻²⁴ In the published studies the target oral dose was 2 mg/kg/day²² and the intravenous dose was 600 mg/m²/monthly for 6 months,²⁴ and these remain the currently recommended doses for clinical use. One of these studies also included maintenance treatment with azathioprine and low-dose prednisolone.²⁴ Observational studies and case series have also supported the use of other agents, such as mycophenolate mofetil^{25,26} or rituximab,^{27,28} and both are being formally evaluated in clinical trials. Optimum duration and frequency of these agents remain controversial, but total duration of treatment with mycophenolate mofetil should probably be at least 2 to 3 years based on the observation of a decline in lung function when oral cyclophosphamide treatment was discontinued after 12 months in the first Scleroderma Lung Study.²² The evidence suggests that the treatment effect of cyclophosphamide seems to be mainly prevention of further disease progression rather than any reversal of existing fibrotic disease, and therefore stabilization of disease should be considered as therapeutic success. Several novel agents have recently been reported to show promise in the treatment of idiopathic pulmonary fibrosis, although none has been formally assessed in SSc-related ILD. Preliminary evidence suggested that the angiokinase inhibitor BIBF, which inhibits downstream response to platelet-derived growth factor, basic fibroblast growth factor, and vascular endothelial growth factor, may prevent decline in FVC, and this is currently being evaluated in ongoing clinical trials.²⁹ Another exciting potential therapy is pirfenidone, a pyridone compound with antifibrotic, antiinflammatory, and antioxidant properties that has been approved for treatment of idiopathic pulmonary fibrosis in Europe and Japan; pirfenidone treatment has led to improvement in FVC and progression-free survival defined as time to at least a 10% decline in percentage of predicted FVC, at least a 15% decline in percentage of predicted DLCO, or death.³⁰ Although there are clear differences in prognosis and histologic findings in different forms of diffuse lung disease, it is likely that the management of lung fibrosis in SSc will be informed by the results from idiopathic pulmonary fibrosis studies.³¹ For selected SSc patients with advanced pulmonary involvement, lung transplantation may be an option. Single-lung transplant is now considered to be the most successful transplantation approach for ILD.³²

Overall approach to management

Management of lung fibrosis is a key aspect of successful care for scleroderma, and it is increasingly recognized that a multidisciplinary approach involving rheumatologists, respiratory physicians, and thoracic radiologists with an interest in SSc is essential. This approach allows early identification and accurate staging of the lung disease and assessment of the likely future course. This is important because, although lung fibrosis represents one of the most important internal organ manifestations of SSc and there are now prospective clinical trial data suggesting that treatment interventions are potentially beneficial, it is also a complication that may in many patients be mild or slowly progressive. Given this fact, it is clear that potentially toxic therapy can be justified only in patients who have severe disease or who are at risk of progression, and treatments that stabilize disease but do not improve outcome need to be used with great circumspection. The first important aspect of management is the detection of lung fibrosis. All SSc patients should undergo regular pulmonary function testing, followed by HRCT if test results show restrictive abnormalities. Other tests that are routinely available include DTPA lung scanning and measurement of serum levels of KL-6, a glycoprotein produced by pneumocytes. Results of these tests, together with simple clinical features such as diffuse skin disease and laboratory abnormalities such as the presence of anti-topoisomerase I antibodies, allow patients at greatest risk of lung fibrosis to be identified. The staging system described earlier permits classification of cases as mild or extensive. Extensive disease is most likely to progress. There is considerable ongoing discussion about the utility of serial investigations and different lung function variables in assessing decline. Exercise capacity as assessed by the 6-minute walk test has been shown to be unreliable in terms of correlation with lung function or other clinical variables.

PULMONARY HYPERTENSION

Pulmonary hypertension (PH) is defined as a mean pulmonary artery pressure at right-sided heart catheterization (RHC) of more than 25 mm Hg. PH represents one of the most important areas of recent therapeutic advance in

SSc. As new therapies emerged and clinical trials were undertaken, better classification and more homogeneous patient groups undoubtedly facilitated the demonstration of treatment benefit—initially the superiority of treatment strategies over placebo and later the usefulness of more complex and sophisticated strategies with combination treatments. It also allowed the flourishing of cohort studies that confirmed the impact of better management and treatment options and led to a tremendous increase in awareness of and interest in PH and especially in the subgroup of postcapillary PAH, which is most relevant to cases of SSc. The first proposed clinical classification of PH appeared in 1973, and the current version developed at Dana Point, California, in 2008 underpinned much of the clinical trial and research strategies (Box 145.2).³³ Its key point is that cases of SSc-associated PH may be classified potentially into one of four groups. The Fifth World Symposium on Pulmonary Hypertension held in Nice in 2013 saw an emerging interest in the concept of borderline PH as a marker for high risk of progression to PH in SSc. Features of the different defined groups (see Box 145.2) may coexist and evolve in the same patient over time. The most important is group 1, PAH. The related conditions that are associated forms of PAH and the cases that are idiopathic are also included in this group. The closely related group of 1', which includes PVOD and pulmonary capillary hemangiosis, may occur in SSc, although the precise frequency is unclear and it may occur in association with more classic precapillary PAH, which is the most prevalent and important form of PH in SSc. PVOD is uncommon in SSc, and excluding PVOD clinically is often difficult. PVOD should be considered in the context of an elevated mean pulmonary artery pressure with low pulmonary capillary wedge pressure and acute clinical worsening with frank pulmonary edema after initiation of PAH-specific therapy. Significant left-sided heart disease leading to postcapillary PH (group 2) may coexist in SSc with low cardiac output or an increased pulmonary capillary wedge pressure above 15 mm Hg on RHC. Diastolic dysfunction is common in SSc patients, and other factors including systemic hypertension and renal impairment may affect cardiac diastolic function. PH can also occur due to lung fibrosis, leading to hypoxia (group 3). This is likely to occur in a minority of SSc patients with extensive lung fibrosis. It is more likely that many patients with PAH who have some lung fibrosis have a predominant vasculopathy more similar to isolated PAH in SSc. Coexistent lung fibrosis may well impact outcome and treatment response. Finally, PH secondary to chronic thromboembolic disease (group 4) may occur, although it is

uncommon in SSc and typically is associated with secondary antiphospholipid syndrome. For these reasons, it is critical that PAH be confirmed by RHC because group 1 PH is probably the most amenable to PAH-specific therapies.

One of the key developments over the last decade is the number of national and international PH registries including REVEAL (Registry to Evaluate Early and Long Term PAH Disease Management)³⁴ and the Mayo registry. These registries aim to advance our understanding of the epidemiology, demographics, clinical course, and disease management of PH. Equally, these registries provide the platform for a rich source of data that will be available to inform the management of PAH in years to come.

Pulmonary arterial hypertension

PAH is defined as a mean pulmonary arterial pressure of more than 25 mm Hg together with a normal (or not elevated) pulmonary capillary wedge pressure (less than 15 mm Hg). It is generally associated with a pulmonary vascular resistance of more than 3 Wood units or more than 240 arbitrary resistance units (ARU). It is essentially an occlusive vasculopathy of the pulmonary arterial tree that leads to increased resistance to pulmonary blood flow with elevated pulmonary pressures. Ultimately this causes strain on the right side of the heart, and this is the main cause of death. It is the most common form of PH in SSc, affecting 82% of SSc patients with postcapillary PH in a recent UK national survey.³⁵ Whether SSc patients with PAH are less able than PAH patients who are otherwise healthy to cope with the increased right-sided heart workload is not yet clear, but this could be one of the potential explanations for why patients with SSc-associated PAH appear to have a worse survival and clinical outcome than patients with idiopathic PAH of the same severity. The observation of pathologic changes over the pulmonary preseptal venules has also fueled speculation that the worse prognosis in SSc-associated PAH may be due to an overlap with PVOD.

The current classification scheme developed at the Dana Point conference³³ simplified the definition of PH and removed formal statements about pulmonary vascular resistance and also exercise-induced PH. The latter change was based largely on the absence of secure robust data about the actual threshold for PH on exercise, because pressures are very dependent on age and fitness. The definitions are summarized in Box 145.3.

Assessment of pulmonary hypertension

When PH is suspected it must be confirmed and the cause ascertained. In many cases of SSc this sequence of events is triggered by clinical suspicion based on symptoms such as worsening dyspnea without other explanation, fatigue, chest pain, and exertional syncope. Clinically, physical findings of a loud pulmonary component of S2 with right-sided heart failure are indicative of late manifestations of PAH. There are, however, few signs of early PAH. Classically, patients with long-standing Raynaud disease, lcSSc, florid telangiectasia with anticentromere antibodies, or positivity for isolated nucleolar-pattern antinuclear antibodies (including anti-U3-RNP or anti-Th/To) are the patients at risk of developing PAH. Investigations may reveal an abnormal result on a lung function test, especially when carbon monoxide transfer factor is diminished in the presence of preserved or relatively preserved lung volumes (assessed by FVC or total lung capacity). An electrocardiogram typically demonstrates signs of right atrial dilatation with right ventricular hypertrophy in those with advanced PAH. Another important investigation is Doppler echocardiography. This may show elevation of the estimated right ventricular systolic pressure (RVSP) or pulmonary artery pressure (adding an estimate of right atrial pressure to the RVSP). The RVSP

Fig. 145.10 Annual screening for the development of pulmonary hypertension is vital in managing systemic sclerosis (SSc). Currently, a combination of symptomatic assessment, Doppler echocardiography, and pulmonary function testing is employed with the need for right-sided heart catheterization depending on the results of these investigations. DLco, diffusion capacity for carbon monoxide; est., estimated; LVEF, left ventricular ejection fraction; Pulm., pulmonary; RVSP, right ventricular systolic pressure; TLC, total lung capacity.

can be estimated from the maximum velocity of the regurgitant jet of the tricuspid valve into the right atrium during ventricular systole. However, this value is just an estimate and may not be computable in some individuals. Thus the Doppler echocardiographic estimation of pressure must be interpreted in a clinical context and with appropriate thresholds for further investigation that will avoid missing cases of PAH. There are other important features of PAH that can be determined by echocardiography, including right atrial or ventricular enlargement and contractility, the tricuspid annular plane systolic excursion, the Tei index, and the presence of pericardial effusion.³⁶ Some estimate of left ventricular function can also be made, and diastolic dysfunction may be apparent. In addition, there are important aspects of the clinical assessment that point toward PH or PAH.

Screening

Annual consideration of the possible presence of PAH should be part of standard care for all SSc patients. The overall frequency of this complication warrants annual screening. Thus at a clinic visit each year the possibility that an SSc patient has PAH must be formally considered. This should involve standardized assessment for relevant symptoms, including breathlessness and exercise capacity, carried out by an experienced physician. Lung function tests should be performed, bearing in mind that this is an important aspect of screening both for PH and for interstitial pulmonary disease and other complications.³⁷ Echocardiography with Doppler estimation of right-sided heart pressure should also be performed. The current screening algorithm used at the authors' center is shown in Fig. 145.10, and similar approaches have been developed, tested, and validated at most centers. Because of the frequency of PAH in SSc and in overlap syndromes with features of SSc (i.e., mixed connective tissue disease) formal screening is generally considered to be mandatory. Recent studies suggest that the frequency of PAH at 5 years from onset of SSc is approximately 8% of cases, and it is well recognized that PAH may present later in the disease, so that up to 12% of SSc patients may ultimately be affected.² There is growing evidence that survival and long-term outcome, together with responsiveness to therapy, is associated with the severity of PAH at diagnosis, and treatments should logically be implemented as early as possible after onset. Thus there is strong support for an effective framework of screening. Risk features for PAH in SSc are summarized in Box 145.4. Sometimes right atrial enlargement or widened pulmonary artery may be diagnosed based on the HRCT appearance, and this is an important consideration and justification for

BOX 145.4 CLINICAL ASSOCIATIONS WITH PULMONARY ARTERIAL HYPERTENSION

- Limited distribution of skin involvement (although also occurs in diffuse cutaneous systemic sclerosis and overlap systemic sclerosis)
- Anticentromere antibodies
- Antifibrillarin antibodies
- Prominent telangiectasia
- Disease duration longer than 3 years

Fig. 145.11 Typical high-resolution computed tomographic (HRCT) appearance of advanced isolated pulmonary arterial hypertension (PAH). Although HRCT generally is performed to determine the presence and extent of interstitial lung disease, there are important abnormalities in this coronal reconstruction that point toward the presence of pulmonary hypertension, especially proximal dilation of the pulmonary vessels and a pulmonary artery main trunk diameter that is greater than that of the ascending aorta. In this case there is little fibrosis and so the diagnosis is likely to be PAH.

systematic investigation in SSc cases. Typical findings in isolated PAH are shown in Fig. 145.11. Currently attempts are being made to better integrate the noninvasive tools that can be used to assess PAH through development of composite scores that might improve detection and diagnosis. One particular goal is to increase the number of appropriate referrals for invasive study by RHC. Scores have been published to integrate tests but require validation and improvement.^{38,39} The preliminary report from the DETECT study, which is conducting a systematic assessment of nearly 500 patients with high-risk SSc to identify developing PAH, provides an evidence-based screening algorithm that incorporates a combination of clinical features, presence of anticentromere antibodies, abnormal electrocardiographic findings, and echocardiographic parameters.⁴⁰

Diagnosis

As outlined earlier, RHC with estimation of mean pulmonary artery pressure together with measurement of the pulmonary capillary wedge pressure or left ventricular end-diastolic pressure is the only way of definitively diagnosing PH and confirming that it is precapillary in origin. Thus noninvasive tests are useful in selecting patients for RHC but cannot make the diagnosis. This is important, because Doppler echocardiographic estimations of pulmonary artery pressure are often wrong. This test is widely used for screening and taking initial steps toward the diagnosis, but in the important range of 30 to 50 mm Hg estimated pressure the rate of false-positive or false-negative test results is around 30%. The negative predictive value of a low RVSP of less than 20 mm Hg and the positive predictive value of an RVSP of more than 60 mm Hg is much better, and this explains the clear statistical correlation between invasive and noninvasive assessment. This should not be taken as indicating that the two investigations are equivalent, and it has been shown in many studies that the error rate is around 30% for Doppler echocardiographic confirmation or exclusion of PH for estimated RVSP in the important range of 30 to 50 mm Hg. When precapillary PH is detected,

exclusion of thromboembolic disease requires nuclear imaging or CT pulmonary angiography to exclude pulmonary embolism. Prospective studies are underway to assess thresholds for noninvasive diagnosis based on echocardiographic and echocardiographic parameters, and the potential value of serum markers such as NT-proBNP) are also being evaluated.⁴¹ Measurement of this marker may potentially help in interpreting borderline echocardiographic findings or assessing the significance of dyspnea but conceptually can be of use only once PH is well established because levels depend on the presence of right ventricular strain. Confounding factors in interpretation include concurrent left ventricular dysfunction and the association of elevated levels of this peptide with extracardiac disease in SSc.

Staging of pulmonary arterial hypertension

Diagnostic RHC provides valuable information about the hemodynamic significance of PAH through examination of variables such as pulmonary vascular resistance, mean pulmonary artery pressure, cardiac index, and right atrial pressure. There is a clear association between more severe disease and poor outcome. In the authors' own cohort, patients who are in the lower half of the population based on pulmonary vascular resistance or who can attain this level of pulmonary vascular resistance within 3 months of starting specific therapy for PAH have significantly better survival. This provides further evidence for the importance of timely diagnosis and initiation of therapy for this treatable complication of SSc.

Assessment of exercise capacity and exercise desaturation by the 6-minute walk test has become a standard method of evaluation of PAH. The distance on this test was the primary endpoint for many of the pivotal trials that have underpinned the licensing of new PAH therapies. The 6-minute walk test, when performed correctly, may provide a relatively inexpensive tool to assess progress in achieving therapy goals with accurate and reproducible results, but there are risks in extrapolating from the findings in idiopathic PAH. In SSc there are many potential confounders that may influence exercise capacity, including musculoskeletal complications, skin disease, pain, and other factors, such as lung fibrosis or cardiac disease. Musculoskeletal deconditioning is especially important, and there is some evidence that this is a dominant feature that influences the result on the 6-minute walk test and that may respond to rehabilitative exercise programs.

There have been recent attempts to integrate clinical and laboratory data in cases of PAH to help better predict outcome. An example is the risk score developed from data collected in the large North American REVEAL registry for PH, although such a score requires prospective independent validation in other patient groups.⁴²

Functional class assessment is a standardized way of assessing exercise capacity. The PH classification is based on the New York Heart Association functional classes for heart failure. The World Health Organization functional classes for PH include syncope as a PH-specific symptom of advanced disease. Assessment of functional class is relatively subjective and the four-point scale is limited, especially because most cases are diagnosed as functional class III despite screening. Additional categories are sometimes used to reflect the features generally considered to indicate good treatment response.³⁵

Biomarkers

The use of biomarkers to direct treatment represents a realistic therapeutic advance in PAH disease management. Serum levels of NT-proBNP correlate well with severity of PAH and may be helpful in screening for PAH.⁴⁰ Similarly, uric acid levels are independently associated with increased mortality in PAH. An increasing number of surrogate markers are under investigation to assess patients and monitor treatment response. Because most biomarkers reflect different pathophysiologic processes in PAH, it is likely that a panel of markers is needed to provide a comprehensive and accurate assessment of the clinical status and hemodynamic endpoints. Biomarkers related to endothelial dysfunction (e.g., von Willebrand factor, dimethylarginines) and inflammation (growth differentiation factor 15, pentraxin 3, osteopontin) may help in understanding the disease but none is used routinely for risk assessment at baseline in patients with PAH. Recently, differences have been described between lcSSc patients with and without PAH in gene expression in peripheral blood mononuclear cells (including the gene for MRC1, a marker of macrophage alternative activation); this increases the prospects of using gene expression signature to evaluate risk of PAH.

Treatment

There have been tremendous advances over the past two decades in the management of PAH. One of the major developments in the authors'

treatment paradigm is a move away from an approach of escalation of therapies in the event of clinical deterioration to one of goal-oriented strategy. The achievements in therapeutics and the evolution in treatment approaches for PAH have led to an improvement in survival in the current era. Recent data from the authors' cohort of over 500 patients with PAH at Royal Free London demonstrated improvement in survival over the last decade (1-year survival rate of 86% in the current cohort compared with 75% a decade ago). Similarly, data from the French registry showed survival rates for PAH patients of 83%, 67%, and 58% at 1, 2, and 3 years, respectively.

The first study that conclusively showed treatment benefit for specific therapy used intravenous prostacyclin (epoprostenol).⁴³ This randomized prospective clinical trial demonstrated significant improvement in exercise capacity and pulmonary hemodynamics in patients receiving epoprostenol compared with those given placebo. Further evaluation of data for this cohort of patients suggests that survival in the long term may be better than in contemporary cases treated with conventional therapy. However, the short serum half-life of epoprostenol (approximately 6 minutes) indicates that the treatment needs to be administered as a continuous infusion via an indwelling central venous catheter. This is associated with considerable inconvenience, risk of infection in up to 15% of patients at 1 year, and risk of sudden cardiovascular compromise when the pump delivery system fails. As well as being given intravenously, prostacyclin may be administered subcutaneously and by inhalation.

The next major advance in management was the use of oral agents for the treatment of SSc-associated PAH. This occurred through the incorporation of patients with PAH who had SSc and other connective tissue disorders into the pivotal clinical trials, which led to licensing of treatments. The first oral therapy developed was the endothelin receptor antagonist bosentan.⁴⁴ Later, other related drugs as well as phosphodiesterase inhibitors were tested. Thus there are now a substantial number of licensed therapies for PAH associated with SSc.

A number of guidelines regarding the treatment of PAH have been published recently, and these should be followed because they are based on evidence and expert consensus and are endorsed by respected and informed specialist societies.⁴⁵⁻⁴⁹ The current recommendations are summarized in Fig. 145.12. The recommendations are essentially similar for the European Respiratory Society/European Society of Cardiology, the American Thoracic Society/American College of Cardiology, and the Dana Point Fourth World Symposium on Pulmonary Hypertension. There is an important goal in these recommendations, which is to try to ensure that therapy is standardized across centers and regions to reflect current best practice while also taking into account the differences in licensed therapies that are available. The authors of all sets of recommendation are experts, and there is an attempt to integrate the best available evidence for treatment benefit with current practice at most centers. It is an important aspect of management that specialist centers be involved in assessment and treatment planning so that therapies are given appropriately. Emphasis is placed on the importance of a multidisciplinary approach to therapy, and the severity of PAH also is taken into account in treatment planning.

Thus, once the diagnosis is confirmed by RHC, patients receive background therapy with anticoagulants, with management of fluid overload or heart failure in advanced cases. Oxygen therapy with the aim of maintaining saturations above 90% may provide symptomatic relief, particularly in patients with significant lung fibrosis. For PAH in association with SSc some centers recommend a formal vasodilator study at catheterization, although the result is very rarely positive and most centers have abandoned this practice. There is no significant difference between iloprost and inhaled nitrous oxide in this test. Only patients who show significant improvement in mean pulmonary arterial pressure and cardiac output are deemed to be valid responders to the vasodilator test, and so the test result needs to be assessed carefully.

For patients in functional class I who have no symptoms, usually only supportive therapy is given. There are now licensed therapies for patients in functional classes II and III, and these should be initiated at diagnosis. One of the oral agents is begun as an initial therapy. An overview of currently licensed PAH-specific therapies is given in Table 145.1. Although some recommendations favor eicosatrienoic acid as initial therapy in patients with connective tissue disorders, there is no strong evidence for its superiority, and it is entirely reasonable to start with either a phosphodiesterase-5 inhibitor or an endothelin receptor antagonist. The key focus should be on evaluating response to therapy because it is important to modify treatment if there is not adequate response. The authors' practice is routinely to perform a repeat RHC if the diagnostic study suggests that the patient has advanced PAH and is in a poor prognostic group based on hemodynamics, with pulmonary vascular resistance above 650 ARU or mean pulmonary arterial pressure above 40 mm Hg. If the values of these variables have not moved

Fig. 145.12 There have been a number of recent publications of evidence-based treatment recommendations for cases of pulmonary arterial hypertension (PAH). These generally are generic for all causes, including other types of PAH not associated with systemic sclerosis (SSc). This algorithm is directed toward SSc-related PAH as outlined in this chapter. ERA, endothelin receptor antagonist; inh, inhaled; IV, intravenously; mPAP, mean pulmonary artery pressure; PCW, pulmonary capillary wedge pressure; PDE5i, phosphodiesterase-5 inhibitor; PF, pulmonary fibrosis; SC, subcutaneously; WHO, World Health Organization. (Modified from Dana Point 2008, ESC/ERS 2009, UK PAH Centres 2008, ACP 2009.)

the patient to a better subgroup at this second study, then combination oral treatment with eicosatrienoic acid and a phosphodiesterase-5 inhibitor is initiated. Less severe cases are followed noninvasively over the first 3 to 6 months with evaluation for substantial improvement in NT-proBNP level if previously elevated, gain in 6-minute walk test distance, and improvement in functional class. Further deterioration prompts addition of a prostanoid, usually subcutaneous or inhaled treprostinil or iloprost. However, in the future oral prostacyclin analogues may be shown to be effective and may be used in a triple-combination oral therapy. There is a growing trend toward the use of combination therapy, especially in patients in the severe stage of the disease. The use of specific therapies in combination make sense in terms of likely synergy through different mechanisms of action, and this approach is often being used. Some limited trial data are already available that confirm

the additional benefit of using specific combinations of PAH drugs, and more evidence is emerging to support this strategy in some cases. At present no trials of combination therapy specifically for patients with SSc-associated PAH have been undertaken, although this subgroup is often included in studies of precapillary PAH. It is hoped that the use of combination treatments specifically in SSc-associated PAH will increase and will be properly evaluated, and that the benefits of a goal-directed step-up approach and an upfront combination strategy will be compared.

Finally, if major progression to functional class IV occurs, then patients are considered for intravenous prostacyclin analogue therapy. Licensed agents include epoprostenol and treprostinil.

Recommendations for cases that are functional class IV at diagnosis generally include intravenous epoprostenol. This is certainly the optimum

■ TABLE 145.1

Licensed therapies available for treatment of pulmonary arterial hypertension

Class of drug	Drug	Route of administration and dosage	Main adverse effects	Comments
Endothelin receptor antagonist	Bosentan	Oral: 62.5 mg twice daily for 1 mo, then 125 mg twice daily	LFT abnormalities in up to 10% and so monthly monitoring required. Potentially teratogenic. Fluid retention and anemia. Reduces oral anticoagulant efficacy.	Nonselective ET _A and ET _B blockade.
	Ambrisentan	Oral: 5 or 10 mg daily	Low risk of LFT abnormalities. Fluid retention common. Anemia. No interaction with oral anticoagulants.	Partially selective ERA with specificity for ET _A .
Phosphodiesterase-5 inhibitors	Sildenafil	Oral: 20 mg 3 times daily	Headache, visual disturbance, epistaxis. Generally well tolerated.	Different formulation licensed for erectile dysfunction.
	Tadalafil	Oral: 40 mg once daily	Headache, visual disturbance, epistaxis. Generally well tolerated.	Longer duration of action than sildenafil.
Prostacyclin analogues	Epoprostenol	Continuous IV infusion: started at 2 ng/kg/min, then titrated upward	Headaches, muscle cramps, diarrhea. Severe worsening if infusion interrupted. Sepsis and other risks from intravenous administration.	Only drug specifically tested in systemic sclerosis-associated PAH in placebo-controlled trial. Reserved for advanced disease.
	Treprostinil	SC or IV infusion: started at 1.25 ng/kg/min, then titrated upward Nebulized inhaled: 18-54 µg 4 times daily	Headaches, muscle cramps, diarrhea. Worsening if infusion interrupted but less immediate than with epoprostenol. Sepsis and other risks from IV administration. Severe local site pain from SC infusion.	Available for IV use and being evaluated for administration by inhaled and oral routes in PAH in clinical trials.
	Iloprost	Nebulized inhaled: 2.5-5.0 µg 6 to 9 times daily	Headaches, muscle cramps, diarrhea.	IV formulation not licensed for PAH.
	Beraprost	Oral: 60 µg daily	Headaches, muscle cramps, diarrhea.	Licensed in Japan.

ET_A, endothelin receptor type A; ET_B, endothelin receptor type B; ERA, endothelin receptor antagonist; IV, intravenous; LFT, liver function test; PAH, pulmonary arterial hypertension; SC, subcutaneous.

current therapy for idiopathic PAH, but fewer data are available for SSc-associated PAH and some centers advocate combination oral therapy for SSc-associated PAH that is diagnosed at this functional level.

Surgical options of heart-lung transplantation or double-lung transplantation are often a particular challenge for SSc patients owing to comorbidity. The presence of gastroesophageal reflux raises the possible risk of post-transplantation obliterative bronchiolitis. Impaired renal function, which is often present albeit not clinically significant, is another barrier, as is osteoporosis, especially in patients who have received long-term corticosteroid therapy. There is always a comprehensive pretransplantation evaluation that addresses these issues. Atrial septostomy can be of benefit in severe cases and is an option in those individuals who have very advanced disease but cannot be considered for transplantation. Benefit is generally short-lived but can be substantial in terms of improved dyspnea and greater exercise capacity. Short-term administration of inotropes has potential in very advanced PAH once other treatment options have been exhausted, although there are particular challenges related to the sensitivity of SSc patients to agents that may provoke peripheral vasospasm.

There are some areas in which SSc-associated PAH needs to be given specific consideration. For instance, it is very unusual for vasodilators to be beneficial in this group of patients, and so long-term treatment with calcium channel blockers is rarely, if ever, appropriate. Although some patients show a short-term decrease in mean pulmonary artery pressure and may have improved cardiac output, in reality long-term responses are very unusual. For this reason, guidelines from the United Kingdom recommend that it not be considered mandatory for the patient to show a vasodilator response test at the time of diagnostic RHC. This may not apply in non-SSc-associated PAH, and so these patients should have a formal vasodilator challenge at diagnosis. Another area of specific consideration is the relatively weak data for the benefit of long-term anticoagulation in SSc-associated PAH. Thus its use is generally a balanced decision made in individual cases. Anticoagulation carries specific hazards in SSc relating to gastrointestinal blood loss due to gastroesophagitis, gastric antral vascular ectasia, and gastrointestinal telangiectasia. In general, when oral anticoagulation is used an international normalized ratio of 2.0 to 2.5 is the recommended target. It should be remembered that a short-term course of antibiotics is often needed for skin or gastrointestinal infection, and this poses an additional challenge. The specific interaction of eicosatrienoic acids and an oral anticoagulant must also be considered in relevant patients.

The selection of first-line agents as a specific targeted therapy for PAH varies among centers. For historic reasons, there is a longer experience with

eicosatrienoic acids than with phosphodiesterase-5 inhibitors in SSc-associated PAH, but this does not necessarily mean that they should always be used as first-line therapy. At present there is no clear evidence that eicosatrienoic acids have different efficacy in SSc-associated PAH, and so the various licensed agents can be considered equivalent.⁵⁰ It is logical to try an alternative eicosatrienoic acid in patients who show liver function test abnormalities when receiving one of these drugs. Once long-term data show that phosphodiesterase-5 inhibitors are equally effective at reducing mortality in SSc-associated PAH, then these could be used as first-line agents. In reality, many patients progress to combination therapy. The recent guidelines are explicit in recommending intravenous epoprostenol in cases of PAH that are diagnosed at the functional class IV level. This is due to the clear benefit in survival in idiopathic PAH. The case for its use in SSc-associated PAH is less clear, although most centers would view this as an appropriate therapy. In the United Kingdom, however, it is often considered appropriate to treat SSc-associated PAH with combination oral therapy at diagnosis and reassess early before moving to intravenous therapy. This is the subject of ongoing analysis.

Disease progression does occur in a majority of these patients and overall the long-term prognosis, although improved, remains poor. Thus there is a major need to develop new treatments, either improvements in currently available PAH-specific therapies or agents targeting novel pathogenic pathways. The number of new potential therapeutics is increasing, and many are currently undergoing clinical trials (riociguat, cicletanine, selexipag, macitentan, and imatinib). Macitentan, a nonselective ET_{A/B} endothelin receptor antagonist, was recently tested in the SERAPHIN phase 3 clinical trial in patients with PAH, including SSc patients.⁵¹ Using a morbidity and mortality composite endpoint (including death, atrial septostomy, lung transplantation, initiation of prostanoid therapy, and other indicators of worsening of PAH), this study found a dose-dependent risk reduction of 30% to 45% in response to macitentan. Other phosphodiesterase-5 inhibitors, including vardenafil, show great promise in improving symptoms, functional status, and hemodynamics and appeared to be well tolerated. Selexipag is an orally available selective prostacyclin IP receptor agonist that exerts greater vasodilatory effect than iloprost and is currently being evaluated in the GRIPHON phase 3 trial with a primary endpoint of time to first clinical event. A clinical trial of the use of oral treprostinil as an add-on therapy to an endothelin receptor antagonist and/or phosphodiesterase-5 inhibitor did not meet its endpoint of improvement in 6-minute walk distance, but results from two additional studies are pending.⁵²

In many cases the outcome of PAH appears to be worse in patients with SSc-associated disease than in patients with equally severe idiopathic PAH. There are a number of potential explanations for this finding, but it does suggest that this group of PAH cases presents a particular treatment challenge.

Another important consideration in the management of SSc-associated PAH is that there are other mechanisms for PH specifically relating to group 2 and group 3 disease that may contribute to outcome. They overlap with those of the 1' group, and there is the possibility that SSc comorbidity, including gut, heart, and renal disease, may impact outcome.

CONCURRENT INTERSTITIAL AND VASCULAR DISEASE

One of the major clinical challenges in assessment and treatment of pulmonary disease in SSc is the potential for multiple complications that may interact and lead to confusion in diagnosis and assessment. This is most apparent in considering interstitial lung fibrosis and PAH. Both complications are sufficiently frequent in SSc that they are likely to occur together by chance in a significant number of individuals. In practice it is usually possible to identify one of these processes as the predominant problem, and this can then be the main focus of management. However, there are challenges in applying data from observational cohort studies or clinical trials,

because most often an attempt is made to use a homogeneous cohort for study, and so cases in which there is the possibility of missed lung fibrosis and PAH are often excluded. Therefore outcome and treatment response data may not be applicable to patients with mixed or coexistent dual pathologic conditions. One example is that in current cohort studies, patients with PAH who have lung fibrosis appear to show blunted response to therapy even though the predominant pathologic condition is PAH rather than PH. Moreover, analysis of the outcome of lung fibrosis based on extent of disease or classification into mild or extensive subgroup is based on data sets from which clinically apparent PH was excluded.

CONCLUSION

In conclusion, although pulmonary complications of SSc have become a justifiable focus of investigation and treatment, it is important to remember that these complications occur in the context of a multisystem disease. Other important manifestations may also be present. For example, cardiac involvement, scleroderma renal crisis, pleural effusion, and chest wall disease arising from fibrosis or skeletal myopathy all may be relevant. In addition, nonlethal complications of SSc are often of greater importance to individual patients than the risk of developing a life-threatening lung manifestation, and so a comprehensive, multidisciplinary long-term care plan must provide the context for management of organ-based disease.

Raynaud phenomenon

■ COLIN BAINES ■ PRADEEP KUMAR ■ JILL J.F. BELCH

- Raynaud phenomenon is an episodic reversible peripheral ischemia usually provoked by cold or emotion.
- Classically, constriction of the digital vessels leads to pallor of the digits reflecting poor or absent blood flow, followed by cyanosis secondary to deoxygenation of static venous blood.
- The recovery phase features reactive hyperemia secondary to a chemical vasodilation with resulting erythema.

HISTORY

Raynaud phenomenon is named after Maurice Raynaud, a French physician who described this condition in his medical thesis *De l'Asphyxie Locale et de la Gangrène Symétrique des Extrémités* published on February 25, 1862.

EPIDEMIOLOGY

In Europe, *Raynaud phenomenon* is the blanket term used to describe any form of cold-related vasospasm, which can be further subdivided into *Raynaud syndrome* when there is an associated disorder and *Raynaud disease* when there is not. However, in the United States the terminology most used is *primary* and *secondary Raynaud phenomenon*. Thus care must be taken when making literature comparisons.

Raynaud phenomenon affects 20% to 30% of young women with an overall prevalence in the population of approximately 10% and a female-male ratio of 9:1.¹ By far the largest group is those with primary Raynaud disease, which typically occurs in young women in their teens and 20s and has a familial predisposition. In contrast, more than 50% of the patients referred to a hospital have an associated underlying systemic disease. Raynaud syndrome may predate systemic illness by up to two decades. Epidemiologic studies have shown familial clustering of Raynaud disease, migraine, and irritable bowel syndrome, which may share a common cause in vasospasm followed by a reactive vasodilatation.

ETIOLOGY

There is a wide spectrum of disease associated with Raynaud syndrome, including connective tissue disorders (CTDs) and, less commonly, drug-induced and atherosclerotic disorders. Significant numbers of predominantly male sufferers have Raynaud phenomenon associated with occupational exposure to vibration.

Most cases of severe Raynaud phenomenon are associated with CTD. Raynaud phenomenon occurs in 98% of patients with systemic sclerosis (SSc) and may be their most pressing clinical problem; it occurs in 85% of patients with mixed CTD, between 10% and 45% of those with systemic lupus erythematosus, 33% of those with Sjögren syndrome, and 20% of those with polymyositis/dermatomyositis. In individuals with rheumatoid arthritis the overall prevalence is similar to that in the general population (10%); however, symptoms tend to be more severe.

Various drugs can precipitate or exacerbate Raynaud phenomenon. Of these, nonselective β -blockers and antimigraine preparations are the most frequent culprits. The newer generation of vasodilating β -blockers, however, does not cause this problem.

Hand-arm vibration syndrome (HAVS) is the most common form of occupational Raynaud phenomenon, with a prevalence of up to 50% in

workers using vibrating machines on a frequent basis. In the older age group, obstructive vascular disease is the most common cause. Sixty percent of cases of Raynaud phenomenon occurring in individuals older than age 60 are atherosclerotic in origin. Other conditions associated with Raynaud phenomenon are listed in [Box 146.1](#).

PATHOPHYSIOLOGY

Raynaud phenomenon predominantly affects the digits, although it may involve the nose, tongue, earlobes, and nipples, as well as other organs. A decrease in lung, esophageal, and myocardial perfusion has been reported after cold challenge, which suggests that vasospasm may be systemic in distribution. Furthermore, the links with migraine, irritable bowel syndrome, and cardiac syndrome X all suggest a common etiology. There are three pathophysiologic mechanisms that may mediate or aggravate these symptoms: (1) neurogenic mechanisms, (2) blood and blood vessel wall interactions, and (3) abnormalities of the inflammatory and immune responses.

Neurogenic mechanisms

The endothelium possesses at least five different adrenoceptor subtypes (α_2A/D , α_2C , β_1 , β_2 , and β_3), which either directly or through the release of nitric oxide (NO) actively participate in the regulation of vascular tone. Vasoconstriction evoked by postsynaptic α_2 -adrenoceptors is strongly implicated in the response to cold in patients with Raynaud phenomenon. Raynaud disease is far more common in women than in men. The constrictor effect of estrogen could also be due to a tonic effect of the hormone on sympathetic nerve traffic, a direct effect on adrenergic signaling, and/or amplification of an adrenergic response by vasoconstrictor prostanoids.

The central sympathetic system has some role in the pathogenesis, because local vibration of one hand induces vasoconstriction in the other, which is abolished by proximal nerve blockade. Moreover, stress-induced vasoconstriction has been extensively reported by those with Raynaud phenomenon, which suggests a central nervous system component. Impairment of central neural habituation of the pattern of cardiovascular response evoked by acute emotional stress has been demonstrated in patients with primary Raynaud phenomenon.² So it can be inferred that, throughout the working day, repeated vasoconstriction must occur in the fingers as part of the response to various stressors. This can facilitate the development of vasospasm in individuals who are susceptible to Raynaud disease. The selective serotonin reuptake inhibitor (SSRI) fluoxetine has been shown to reduce the frequency and severity of vasospastic episodes in patients with Raynaud disease and to increase the rate of rewarming after a cold challenge. Because the inhibition of reuptake by an SSRI would be expected to increase the plasma concentration of serotonin, which has vasoconstrictive properties, it is most likely that this agent achieves its beneficial effects by acting within the central nervous system. In addition, a deficit of nerves containing calcitonin gene-related peptide (a potent vasodilatory neuropeptide) has been shown in primary Raynaud disease, but it is not clear whether this is a primary abnormality or secondary to repeated vasospasm.

Raynaud may occur with carpal tunnel syndrome, but this may merely reflect the link between two diseases that frequently coexist in the population, particularly in those with HAVS.

Blood and blood vessel wall interactions

Although CTD is associated with some structural damage of the digital arteries and microvasculature, in primary Raynaud disease only subtle microvascular abnormalities occur, which are not visible using capillary

BOX 146.1 CONDITIONS ASSOCIATED WITH RAYNAUD PHENOMENON**Immune mediated**

- Systemic sclerosis (90%)
- Mixed connective tissue disease (85%)
- Sjögren syndrome (33%)
- Systemic lupus erythematosus (10%-45%)
- Polymyositis/dermatomyositis (20%)
- Rheumatoid arthritis (10%-15%)
- Cryoglobulinemia and cryofibrinogenemia (10%)
- Arteritis (e.g., giant cell arteritis, Takayasu arteritis)
- Antiphospholipid syndrome
- Primary biliary cirrhosis

Occupation related

- Cold injury (e.g., in frozen-food packers)
- Polyvinyl chloride exposure
- Vibration exposure
- Ammunition work (outside job)

Obstructive vascular disease

- Atherosclerosis
- Microemboli
- Thromboangiitis obliterans (50%)
- Thoracic outlet syndrome (e.g., cervical rib)
- Walking-crutch pressure
- Diabetic microangiopathy

Metabolic disorders

- Hypothyroidism
- Carcinoid syndrome

Drug induced

- Antimigraine compounds
- β -blockers (particularly nonselective)
- Cytotoxic drugs
- Cyclosporine
- Bromocriptine
- Sulfasalazine
- Minocycline
- Interferon- α
- Interferon- β
- Cocaine abuse

Infections

- Chronic viral liver diseases (hepatitis B and C)
- Cytomegalovirus infection
- Parvovirus B19 infection

Miscellaneous

- Complex regional pain syndrome type I
- Fibromyalgia syndrome
- Postviral fatigue syndrome (myalgic encephalitis)
- Toxin exposure
- Polycythemia
- Paraproteinemia
- Arteriovenous fistula
- Anorexia nervosa
- Neoplasm

Percent values are percentage of patients with the given disease who have Raynaud phenomenon.

microscopy.³ The endothelium is a functioning organ that releases substances important in maintaining blood flow. These include vasodilators such as prostacyclin (prostaglandin I_2 [PGI_2]) and NO, vasoconstrictors such as endothelin-1, and a variety of mediators of coagulation and inflammation. When the endothelium is impaired there is an imbalance of these substances, resulting in a vasoconstrictor, proinflammatory, and procoagulant endothelium that may lead to vascular damage. Abnormal endothelial responses to both endothelium-dependent and endothelium-independent vasodilatation have been found in patients with primary Raynaud phenomenon; however, in patients with Raynaud syndrome secondary to SSc, this abnormality is limited to the endothelium-dependent vasodilatation. It seems, therefore, that although secondary Raynaud phenomenon is associ-

ated with endothelial damage, in primary Raynaud phenomenon the mechanism of vasospasm may be related to smooth muscle contraction.

A reduction of NO, a potent vasodilator produced by the endothelium, may be involved in the pathogenesis of Raynaud phenomenon, and this can be clinically relevant because blood flow is improved when NO is administered therapeutically. Moreover, plasma levels of the endogenous NO synthase inhibitor asymmetric dimethylarginine have been found to be significantly higher in secondary than in primary Raynaud phenomenon, which further suggests involvement of the NO pathway in its pathogenesis.

It has also been shown that cooling-induced vasospasm is mediated by protein tyrosine kinase in Raynaud phenomenon secondary to SSc, with attenuation of spasm by its inhibitors providing an exciting new therapeutic target.⁴

Levels of other substances produced by the endothelium have also been reported to be abnormal in secondary Raynaud phenomenon. These include elevated levels of endothelin-1, angiotensin II (in diffuse SSc but not in limited SSc), the prothrombotic factor VIII/von Willebrand factor, as well as activators of the coagulation pathway and markers of impaired fibrinolysis. This may suggest that the endothelium plays an important role in the pathogenesis of secondary Raynaud phenomenon by promoting vasoconstriction and thrombosis.

In primary Raynaud phenomenon, however, the evidence for endothelial impairment is less clear, with some studies reporting raised levels of von Willebrand factor in affected individuals but others failing to demonstrate any differences from healthy control subjects. Only endothelin-1 and tyrosine kinase have been postulated as being important in primary Raynaud phenomenon because levels have been found to increase more in affected individuals than in control subjects after a cold challenge.

Blood cellular elements may have a pathologic role in Raynaud phenomenon. The platelets exhibit increased aggregation, releasing the vasoconstrictor and platelet aggregant thromboxane A_2 and other platelet-release products such as transforming growth factor- β and platelet-derived growth factor. The red blood cells appear to be stiff and rigid and thus can occlude the microcirculation. The white blood cells, which, when activated, release prothrombotic free radicals, become very stiff and aggregate, and this leads to a further reduction in blood flow. Some of these changes are likely to be a consequence of the vasospasm of Raynaud phenomenon rather than a cause, but they may augment the symptoms, and their attenuation is a potentially important feature in the drug management of this disorder.

Abnormalities of the inflammatory and immune responses

Disordered immune and inflammatory processes occur in the majority of severe cases of Raynaud phenomenon via their association with the CTDs but also occur in HAVS, which has no clear immune or inflammatory basis. Tumor necrosis factor, lymphotoxin, and phagocyte/macrophage- and T cell-derived proteins, along with immune complex deposition in the vessel wall, are likely to be activated in vascular damage seen in Raynaud syndrome.

Thus there are three clear pathways for promoting the decreased blood flow seen in Raynaud phenomenon. It has still to be resolved which are cause and which are consequence, but it seems that a combination of the factors is involved in the development of Raynaud phenomenon.

CLINICAL FEATURES

Detailed history taking and physical examination are essential for making the diagnosis, finding any associated underlying causes, assessing the likelihood of progression to CTD, and deciding on the most appropriate management. A detailed occupational history allows a diagnosis of HAVS. Drug history is equally important, and it should be noted that even the cardioselective β -blockers can produce a degree of peripheral vasoconstriction in susceptible individuals.

As documented earlier, Raynaud phenomenon is classically manifested by blanching of the affected part (pallor) (Fig. 146.1), followed by cyanosis and then rubor; however, this typical triphasic color change is not necessarily present in all patients, with some experiencing biphasic or monophasic color change. Generally, it is accepted that blanching must be present to allow a diagnosis of Raynaud phenomenon. Symptoms include numbness, cold, and pain secondary to ischemia, which can be severe enough to result in digital ulceration, gangrene, and loss of digits. During the reactive hyperemic stage, patients experience an unpleasant burning sensation or tingling. The most severely affected patients may experience year-round restrictions in daily activity.

Fig. 146.1 Raynaud phenomenon in a patient with systemic sclerosis. The asymmetric involvement and the presence of telangiectasia point to a secondary cause. Digital pitting and scarring is one of the main criteria for the diagnosis of systemic sclerosis.

BOX 146.2 FEATURES SUGGESTIVE OF PROGRESSION OF RAYNAUD PHENOMENON

Clinical

- Older age at onset (>35 years)
- Recurrence of chilblains as adult
- Vasospasm all year round
- Asymmetric attacks (see Fig. 146.1)
- Sclerodactyly or any other sign of connective tissue disease
- Digital ulceration
- Finger pulp pitting scars

Laboratory

- Increased levels of inflammatory markers
- Detection of autoantibodies
- Increased level of von Willebrand factor antigen

Nail-fold microscopy

- Abnormal vessels

The predictors for increased attack rate, severity, and pain are low average daily temperature, stress, older age, female gender, and an underlying cause, particularly CTD. The presence of certain clinical features may suggest a greater likelihood of disease progression to overt CTD (Box 146.2). For instance, sclerodactyly and pitting scars over the finger pulp are associated with later development of CTD (Fig. 146.2).

Patients who experience Raynaud phenomenon for the first time in their third and fourth decades are at high risk of developing CTDs. In very young children, an underlying CTD should also be considered, especially if the symptoms include blanching and are severe. Cyanosis alone is a common benign finding in young children. In SSc, if Raynaud phenomenon precedes the CTD by years, the limited form of the disease is more likely; conversely, the rapid appearance of the symptoms of SSc tends to predict diffuse SSc. Systemic evaluation should concentrate on the presence of migraine (or a family history of migraine), vasospastic angina, and a family history of the disorder (usually markers of primary Raynaud phenomenon). Elderly patients who experience Raynaud phenomenon for the first time usually have underlying atherosclerosis. A full physical examination should be performed to look for any obstructive vascular disease and for signs of associated autoimmune conditions. Simple blood pressure measurements in both arms can help to detect significant occlusive vascular disease above the brachial artery. Signs and symptoms of carpal tunnel syndrome should be actively sought, because sometimes releasing the median nerve can improve

Fig. 146.2 Digital pitting and scarring and sclerodactyly are commonly associated with systemic sclerosis. These lesions fulfill two of the three main criteria for systemic sclerosis; the third criterion is pulmonary interstitial fibrosis.

the symptoms of Raynaud phenomenon. Livedo reticularis could point to cold agglutinin disease, antiphospholipid syndrome, or underlying CTD. Patients with abnormal findings on nail-fold microscopy are much more likely to develop a CTD.

INVESTIGATIONS

Investigations in patients with Raynaud phenomenon have two functions: (1) to confirm the diagnosis and (2) to look for underlying secondary causes or associated conditions.

Diagnosis of Raynaud phenomenon

In the majority of cases the diagnosis of Raynaud phenomenon can be made from the clinical history. However, objective measures of blood flow may be needed in rare situations such as when the patient is unable to give a clear history, when occlusive vascular disease is present and the contribution of vasospasm to the clinical problem needs to be determined, and when documentation is required for medicolegal reasons in HAVS.

Many different techniques can be used to measure blood flow to the digits. In clinical practice, measurement of digital systolic blood pressure before and after local cooling of the hands in cool water at a temperature of approximately 15°C is widely used because of its simplicity. A decrease in pressure of more than 20 to 25 mm Hg is usually significant. This technique can give false-negative results unless precautions are observed. First, the patient must be warm before the recordings are made with the starting digital pressure as near brachial pressure as can be achieved. Second, in premenopausal women, assessment should be avoided in midcycle, because poor blood flow can occur at the time of ovulation. Third, all vasoactive medications should be stopped 24 hours before the test and the test should be avoided when the patient is in the reactive hyperemic phase. Ideally, patients should not have had a vasospastic attack on the day of the test. Therefore, although cold challenge is a good clinical diagnostic test, its false-negative rate precludes its use in compensation cases such as those involving HAVS, and in these cases thermal esthesiometry and vibrotactile thresholds are used instead.

Thermography and laser Doppler flowmetry are other methods used to help in the diagnosis. However, these methods have disadvantages and are usually unnecessary, and they are used mainly in the research setting.

Investigations for secondary causes

More than 50% of patients with Raynaud phenomenon who are referred to a hospital have an associated underlying disease; therefore it is essential to look carefully for any underlying cause. More importantly, early intervention could alleviate the problem, as in patients with vibration exposure or those who take vasoconstrictor drugs. An obvious associated disorder may be easily detected, but difficulty arises in diagnosing early CTDs due to the lag period between development of Raynaud phenomenon and the other features of the CTD.

Blood biochemistry testing, including thyroid function tests and a full blood cell count, should be performed. A normochromic, normocytic or microcytic anemia of chronic disease can be found in patients with CTDs. The inflammatory markers such as erythrocyte sedimentation rate, plasma

Fig. 146.3 Nail-fold microscopy. (a) Normal capillaries. (b) Tortuous and enlarged capillaries in systemic sclerosis.

viscosity, and C-reactive protein level are usually normal in primary Raynaud phenomenon, but they may be increased in secondary disease. Measurement of creatinine concentration, determination of estimated glomerular filtration rate, and urinalysis help in detecting early renal disease in CTD, diabetes, or atherosclerosis. Thoracic outlet chest radiography can reveal whether a bony cervical rib is present and show if there is any basal lung fibrosis, which may be seen early in CTDs. However, because the rib may be fibrous, if there is a high clinical suspicion of a cervical rib despite a negative finding on chest radiograph, then it is usual to progress to thoracic outlet magnetic resonance angiography.

Immunologic tests may help to detect any immunopathologic origin for secondary Raynaud phenomenon, and these tests and their specific disorders are covered elsewhere. Detection of cold-precipitated proteins can help in the diagnosis of cryoglobulinemia and cryofibrinogenemia. Increased levels of von Willebrand factor antigen tends to occur in patients with secondary Raynaud phenomenon. Focus is placed on the role of investigative techniques that may help to distinguish between primary and secondary Raynaud phenomenon—in particular, Raynaud phenomenon related to SSc, in which pathognomonic changes of tortuosity and dropout are seen. Nail-fold microscopy is useful to examine morphologic and functional changes of the microcirculation and may help to point to Raynaud phenomenon secondary to CTD, especially when associated with positive serum antibody test results (Fig. 146.3). Nail-fold videocapillaroscopy has emerged as an extremely useful and important tool in identifying CTDs. This technique involves direct visualization of the nail-fold capillary vessels with a digital camera attached to a computer. In combination with negative results on immunologic testing, normal nail-fold videocapillaroscopy findings are very suggestive of primary Raynaud phenomenon.

MANAGEMENT

Not all patients experiencing digital vasospasm require drug treatment, but potential prescribers should be aware that the severity of the pain produced

TABLE 146.1
Drugs commonly used in Raynaud phenomenon

Drug	Dosage
Oral	
Nifedipine retard (or other calcium channel blocker)	10-20 mg bid or tid
Naftidrofuryl oxalate	100-200 mg tid
Inositol nicotinate	1 g tid or inositol nicotinate forte 1.5 g bid
Thymoxamine	40-80 mg qid (stop after 2 wk if no response)
Intravenous	
Iloprost	Start infusion (peripheral line) at 1 µg/hr; increase by 1 µg every 30 min until maximum tolerable dose reached (maximum dosage should not be >3 µg/hr). Infusions are given over 6 hr each day for 3-7 days on each occasion.
Prostaglandin E ₁	60 µg in 250-mL physiologic infusion over 3 hr daily for 5-6 days. This can be repeated every 6 wk to cover cold weather in severe cases, especially if associated with critical ischemia or digital ulceration, and should be given via a central line.

by vasospastic attacks and the degree of interruption that patients may experience in their normal daily routine may be profound.

General measures

Education and patient avoidance of triggers are key. Lifestyle measures such as wearing gloves when handling frozen food should be adopted. It is essential that patients stop smoking and, where applicable, avoid vibration exposure. Initial treatment in mild disease is conservative, and drug treatment is avoided. A specialist rheumatology nurse and occupational therapist can provide useful advice, as can patient self-help groups. It is important to advise patients about protecting themselves from the cold. Making simple suggestions such as keeping the trunk warm and providing occupational therapy aids such as key holders to use when the fingers are numb can help. Electrically heated gloves and socks and chemical hand warmers are the perfect solution for some patients.

In the case of HAVS, early diagnosis and early discontinuation of vibration exposure may resolve the problem. Cessation of any vasoconstrictor drugs the patient is taking is essential. Although the contraceptive pill has been linked anecdotally to the development of Raynaud phenomenon, this has never been conclusively demonstrated. It is the authors' policy not to discontinue the contraceptive pill or hormone replacement therapy unless it is clearly related to the patient's Raynaud phenomenon. In the management of digital ulceration in patients with severe Raynaud phenomenon, it is essential to treat any infection aggressively and quickly. In SSc inflammation may be restricted and thus may be missed unless specifically sought.

Drug treatment

Patients whose symptoms are severe enough to cause interference with either their social or work lifestyle should be considered for drug treatment (Table 146.1).

Calcium channel blockers

Dihydropyridine calcium channel blockers, in particular nifedipine, in a long-acting preparation (e.g., nifedipine retard) have now become the gold standard. The short-acting preparations produce violent vasodilatory adverse effects and their action lasts only a few hours. Nifedipine's mechanism of action is predominantly vasodilation, but it also has antiplatelet and possibly other antithrombotic effects. The dosage ranges from 10 to 20 mg two or three times daily; the drug should be introduced very gradually: 10 mg at night for 2 weeks, then in the morning for 2 weeks, then twice a day, and so on. Nifedipine has been found to be useful in decreasing the frequency and severity of vasospastic attacks and improves the objective measures of blood flow after cold exposure. Its use, however, can be limited by the vasodilatory adverse effects to which patients with Raynaud phenomenon appear very susceptible, particularly those patients with primary disease. These effects usually disappear with continued treatment, and therefore,

unless they are intolerable, the patient should persevere for at least 2 weeks before stopping the drug. If adverse effects necessitate discontinuation, other calcium channel blockers such as amlodipine or lercanidipine can be tried.

Two meta-analyses have been published looking at the efficacy of calcium channel blockers in primary Raynaud phenomenon and Raynaud phenomenon secondary to SSc. These showed a 33% and 35% reduction in severity of the attacks in primary and secondary disease, respectively, as well as a moderate reduction in the frequency of attacks.^{5,6}

Other vasodilators

The use of other vasodilators in Raynaud phenomenon remains controversial, because most studies have been small or uncontrolled. Inositol nicotinate (a nicotinic acid derivative) and naftidrofuryl oxalate (a mild peripheral vasodilator with a serotonin receptor antagonist effect) have produced some encouraging results in mild to moderate disease, as has thymoxamine. Another role of these medications is as adjuncts to calcium channel blockers when adverse effects prevent the achievement of a high dosage of the latter. These drugs may take up to 3 months to produce their effects, which suggests that their action in Raynaud phenomenon may be through other mechanisms. Moreover, their vasodilatory adverse effects can also be a problem.

In a meta-analysis, prazosin, an α -blocker, was found to have modest effect in the treatment of Raynaud disease secondary to SSc.⁷ Thus prazosin could be considered for those with concomitant hypertension or as an extra option in those who cannot tolerate calcium channel blockers.

Losartan, an angiotensin II receptor antagonist, has been shown in a randomized controlled trial to be modestly effective in treating Raynaud phenomenon associated with CTD.⁸ There is no similar study assessing response in primary Raynaud phenomenon, however.

Newer oral vasodilating therapies have been investigated with some promise. Phosphodiesterase-5 inhibitors (sildenafil, tadalafil, and vardenafil) have all shown promising results.⁹ A recent meta-analysis concluded that phosphodiesterase-5 inhibitors appear to have significant but moderate efficacy in secondary Raynaud phenomenon,⁹ but a large randomized controlled trial is also needed. The limitations of these studies are their relatively short duration and their use of predominately secondary Raynaud phenomenon patient cohorts. Thus the role these drugs will play in therapeutic regimens is not yet established.

Prostaglandins

Both prostacyclin (PGI₂) and alprostadil (PGE₁) have potent vasodilatory and antiplatelet properties. Treatment with PGI₂ and PGE₁, however, requires intravenous administration through a central line, and both are unstable agents. Thus more stable analogues such as iloprost have been evaluated.

Iloprost

A number of double-blind placebo-controlled studies as well as a meta-analysis¹⁰ of iloprost infusion given intravenously have shown benefit. In addition to its vasodilatory and antiplatelet effects, iloprost has been shown to downregulate lymphocyte adhesion to the endothelium. Compared with nifedipine, it was found to have the same effect in reducing the frequency of vasospastic attacks but was more effective in healing digital ulcers and appeared to produce fewer adverse effects. Iloprost should generally be considered as a second-line treatment of vasospasm but is the first choice for those who have critical ischemia or severe digital ulceration.

Oral and transdermal prostaglandins

Studies of orally active prostacyclin analogues have yielded conflicting results. Treatment with cicaprost proved disappointing, whereas the evidence supporting the use of oral iloprost in Raynaud phenomenon is less clear. Neither high nor low doses were better than placebo in decreasing attacks in Raynaud disease secondary to SSc. Patient opinion, however, tended to favor high doses of iloprost compared with placebo.

Reports of the oral use of limaprost, an alprostadil analogue, in small numbers of patients have been encouraging, but these findings have not been replicated in larger trials. Prostaglandin delivery through the skin has also been studied, but no transdermally applied prostaglandin has achieved license status as yet.

Alprostadil

A study comparing PGE₁ (alprostadil) with iloprost has shown similar benefits for the two drugs in the management of Raynaud phenomenon secondary to CTDs.¹¹ Alprostadil could be considered in patients who experience significant adverse effects from iloprost and cannot tolerate the drug. PGE₁α cyclodextrin has been reported to improve Raynaud phenomenon symptoms, severity of attacks, and healing of digital lesions in SSc patients.

Other medical therapies

Endothelin-1 receptor antagonists also have been investigated. Bosentan has been evaluated for treatment of digital ulceration secondary to SSc, and some benefit has been seen.¹² Evidence supporting its use in Raynaud phenomenon alone is lacking. Furthermore, in addition to the vasodilatory adverse effects common with other drugs, the possibility of liver toxicity has to be considered, and the results of a current major trial are awaited.

The following agents or procedures have been found effective in small studies and need validation: (1) fluoxetine, an SSRI (another serotonin antagonist, ketanserin, was found not to be beneficial for Raynaud disease secondary to SSc¹³); (2) ginkgo biloba (a second larger study did not report efficacy¹⁰); (3) transdermal glyceryl trinitrate patches (may be of some help, but their use may be limited by the frequent occurrence of headaches); (4) digital botulinum toxin injections (may be effective in severe Raynaud phenomenon and cases of digital ulcer¹⁴); (5) high-dose statins (especially in elderly patients with Raynaud disease who have atherosclerosis¹⁵).

Surgery

Operations to remove part of the terminal phalanx and occasionally amputations are necessary in cases of severe ischemia, but with the advent of iloprost this is becoming infrequent. Raynaud phenomenon secondary to an atherosclerotic occlusion or stenosis may benefit from endovascular intervention. In Raynaud phenomenon secondary to carpal tunnel syndrome, surgical decompression has been shown to improve the symptoms significantly, but whether this is through decreased paresthesia or true improvement of blood flow is unknown.

Conventional upper limb sympathectomy via open surgery is invasive and associated with a high relapse rate and poor response patients with Raynaud syndrome. However, a few studies suggest that thoracoscopic sympathectomy may be successful, particularly in cases of resistant digital ulcers, despite some untoward effects. The longer-term results, however, have yet to be evaluated, and this operation is now performed infrequently. Chemical thoracic sympathectomy (by injection of 5% phenol into the second or third thoracic sympathetic ganglion) may be a safe, minimally invasive procedure, and a good success rate in Raynaud syndrome was reported in one series,¹⁶ but no further work has been published and so this treatment also requires further evaluation.

Localized digital sympathectomy enjoyed some support initially because earlier results were encouraging; however, again further work is required in this area because the relapse rates are high and the associated local tissue trauma can be a problem. Periarterial sympathectomy of the radial and ulnar arteries may have a role in treatment of refractory Raynaud phenomenon, but only small case series have been reported. Convincing published evidence is still absent for upper limb sympathectomy; however, it should be remembered that sympathectomy still has an important role in the treatment of Raynaud phenomenon affecting the feet.

CONCLUSION

Raynaud phenomenon is a common condition, and until recently its management was difficult. Careful clinical history taking, physical examination, and selected investigations allow correct diagnosis and its categorization as primary or secondary. This should be done using all available information and the most up-to-date investigations. Not only does this allow early and appropriate detection of serious medical conditions, but it also provides appropriate reassurance for patients who have primary Raynaud phenomenon. When Raynaud phenomenon occurs as a primary disease, it is usually mild, with symmetric involvement and no laboratory test abnormalities, and may need no drug treatment. Features suggesting secondary Raynaud syndrome include painful attacks, ischemic digital ulcers, asymmetric attacks, a positive autoantibody test result, abnormal nail-fold capillaries, and increased levels of inflammatory markers. Therapeutic management of patients requires individualization of drug therapy depending on the clinical presentation. Patient opinion should always be considered, and appropriate education is the cornerstone of therapy. The prospect of new therapeutic agents and extended licenses for current therapies does suggest a degree of optimism for the future treatment of Raynaud phenomenon.

Localized scleroderma and scleroderma-like syndromes

■ ROBERT W. SIMMS

- Skin induration, the hallmark of systemic sclerosis, can also occur in localized forms of scleroderma, as well as in conditions unrelated to scleroderma or systemic sclerosis. These scleroderma-like syndromes can be classified as “scleroderma variants.”
- The scleroderma variant conditions are unrelated to scleroderma but can be confused with it. This heterogeneous group includes diffuse morphea, eosinophilic fasciitis, scleromyxedema, scleredema, eosinophilia myalgia syndrome, and nephrogenic systemic fibrosis.
- In contrast to systemic sclerosis, the scleroderma variant conditions are rarely associated with sclerodactyly or Raynaud phenomenon, and serum autoantibodies do not occur. However, internal organ involvement may be present and might be associated with plasma cell dyscrasia and eosinophilia.
- The scleroderma variants require accurate diagnosis and different approaches to treatment. Accurate diagnosis may require a full-thickness skin biopsy specimen and careful histopathologic examination with the use of special stains.

A variety of disorders are characterized by sclerosis and induration of the skin, including systemic sclerosis (systemic scleroderma), localized scleroderma (including the subtypes morphea and linear scleroderma), and conditions that mimic systemic sclerosis (Box 147.1). These so-called scleroderma variants might pose significant diagnostic challenges for clinicians and may include localized forms of skin sclerosis, scleredema, scleromyxedema, eosinophilic fasciitis, nephrogenic systemic fibrosis, and chronic graft-versus-host disease (GVHD). A number of drugs (L-tryptophan, bleomycin, and most recently taxane) and environmental exposures (toxic oil syndrome) also produce mimics of scleroderma. Additionally, diabetes and other metabolic conditions may produce skin induration that may be confused with scleroderma. Typically, the scleroderma mimics are not associated with Raynaud phenomenon, nail fold capillary abnormalities such as capillary dropout, capillary dilation or vascular ischemia, calcinosis, or autoantibody formation, which are hallmarks of scleroderma. Other key features that can be used to distinguish between systemic sclerosis and the scleroderma variants are listed in Table 147.1. Careful assessment of the distribution and quality of dermal involvement, history of Raynaud phenomenon, appropriate antibody testing, and full-thickness skin biopsy will generally distinguish these conditions.

LOCALIZED FORMS OF SCLERODERMA

Localized scleroderma is characterized by sclerosis that is confined to the skin and occurs in two principal types that are distinguished by the morphology of the dermal lesions: *linear scleroderma* and *morphea*. *Linear scleroderma* is characterized by the presence of longitudinal bands of skin sclerosis, whereas *morphea* occurs as circumscribed oval plaques. A special form of linear scleroderma involving the head and face, *scleroderma en coup de sabre*, may produce severe facial and skull deformity, as well neurologic abnormalities.¹ Several different subtypes of morphea have been described, including the most common *plaque morphea*, *deep morphea*, *diffuse morphea*, and *pansclerotic morphea*. Additional rare conditions considered within the morphea spectrum include *keloidal or nodular morphea* (sclerotic papules or plaques that resemble keloidal scars), *atrophyoderma of Pasini and Pierini* (depressed hyperpigmented plaques with a sharp border and lacking inflammation and

induration), and *lichen sclerosus et atrophicus* (atrophic white or shiny plaques that may show follicular plugging).² Linear scleroderma tends to be more common in children, whereas morphea is more prevalent in adults.² The estimated annual incidence is 2.7 per 100,000 with a prevalence of 50 per 100,000; the age at onset is about 46 years, and the female-to-male ratio is 2.6.³ Misdiagnosis and delay in treatment appear to be common, especially in children with localized scleroderma.⁴

Morphea

The most common type of morphea lesion is *plaque morphea*, which accounts for approximately 50% of all cases of morphea.³ These lesions typically consist of slowly enlarging single or multiple circumscribed plaques on the trunk or extremities. Initially, they may be erythematous or have a violaceous border but generally become progressively more hyperpigmented over time (Fig. 147.1). Involved skin becomes shiny and lacks sweat glands and hair follicles. Histologically, the early lesions may show a dense inflammatory infiltrate composed of lymphocytes, macrophages, plasma cells, eosinophils, and mast cells. Later stages are characterized by little inflammation and by deposition of collagen extending from the reticular dermis to more superficial structures—indistinguishable from biopsy findings in patients with systemic sclerosis.²

Deep morphea or morphea profunda

Comprising several clinical entities in which inflammation and sclerosis occur in the deep dermis, panniculus, fascia, and even superficial muscle,⁵ deep morphea (or morphea profunda) includes *disabling pansclerotic morphea of children*.⁶ This rare condition is the most aggressive and severe form of morphea because of its propensity to involve deep subcutaneous tissue, fascia, muscle, and bone.⁶⁻¹⁰ It is frequently associated with significant disability and deformity despite intervention.⁶ Chronic ulcers complicating pansclerotic morphea may evolve into squamous cell carcinoma.¹¹

Generalized or diffuse morphea

Characterized by widespread skin involvement with multiple indurated plaques, hyperpigmentation, and frequent muscle atrophy, generalized or diffuse morphea accounts for approximately 15% of all cases of morphea³ (Fig. 147.2). Diagnostic criteria differ among investigators; Takehara and Sato¹² suggested two or more of the following criteria: (1) four or more lesions larger than 3 cm in diameter, irrespective of whether they are of the morphea or linear type, and (2) involvement of two or more of seven areas of the body, the seven areas being the head and neck, the right upper extremity, the left upper extremity, the anterior part of the trunk, the posterior part of the trunk, the right lower extremity, and the left lower extremity.

The presence of a variety of autoantibodies, including antinuclear antibodies and antibodies to histone, nucleosome, U3-RNP, fibrillin, topoisomerase II, and cardiolipin, suggests that morphea is an autoimmune disorder.¹² Additionally, the cytokine profile of morphea lesions involves type 2 helper T-cell activation and overexpression of profibrotic cytokines such as transforming growth factor- β and connective tissue–derived growth factor, similar to the profile seen with systemic sclerosis.^{2,13-15}

Treatment of morphea has included topical tacrolimus, methotrexate, cyclosporine, imatinib, mycophenolate mofetil, ultraviolet A and retinoic acid, and bosentan.¹⁶⁻²⁷ Assessment of efficacy is difficult given the rarity of the condition and slow progression in most cases, and consensus has not been reached regarding standardized assessment. Methotrexate is the most widely used agent for progressive disease; anecdotal reports indicate that it may result in regression of localized lesions.²⁷ The choice of therapy should be based on factors such as activity of the disease, depth of involvement, area of involvement, and rate of progression. Systemic treatment is thought

to be indicated with subcutaneous involvement, rapid progression, and involvement of functionally or cosmetically sensitive areas.²⁸

Linear scleroderma

Linear scleroderma is considered in some classification schemes as a form of morphea (linear morphea) but is best viewed as a separate entity given its clinical and morphologic characteristics.²⁹ Linear scleroderma occurs most commonly in children and adolescents, in whom it accounts for most cases of localized scleroderma, and much less commonly in adults.^{3,30} The typical lesion develops insidiously as a linear band of sclerotic hypopigmented or hyperpigmented skin beginning on the extremities. It may extend through to the underlying dermis, subcutaneous tissue, muscle, and bone and produce significant deformity. When linear scleroderma involves the face or scalp, it is termed *en coup de sabre* and is related to Parry-Romberg syndrome, a condition associated with hemifacial atrophy of tissue below the forehead with little involvement of the skin. Both *en coup de sabre* and Parry-Romberg syndrome may be associated with central nervous system, ocular, and dental abnormalities. A retrospective study of both conditions in 54 patients seen over a 20-year period from 1984 to 2004 at the Mayo Clinic found that both conditions frequently coexist and are often bilateral, thus attesting to the close relationship between *en coup de sabre* and Parry-Romberg syndrome.³¹ Seizures were found to occur in 13% of patients with both syndromes.³¹ Treatment of linear scleroderma most often involves the use of methotrexate or antimalarial agents, but cyclosporine and tissue allografts have also been used.^{16,23,32} A recent report indicated successful application of adipose-derived regenerative cell-enriched fat grafting for treatment of the *en coup de sabre* deformity.³³ A systematic review suggested that phototherapy, methotrexate/systemic corticosteroids, calcipotriene, and

TABLE 147.1
Distinguishing features of scleroderma and scleroderma-like conditions

Condition	Skin changes and distribution	Extradermal involvement	Dermatopathology	Other
Localized scleroderma	Amorphous plaques (morphea) or lines involving the face (linear) and extremities and sparing the fingers	None	Dermal sclerosis, mononuclear inflammation	Linear especially common in children, autoantibodies common
Scleredema	Trunk, back, neck	Rare	Swollen collagen bundles, mucin accumulation	
Scleromyxedema	Induration, sclerodactyly Limited mouth opening	Rare	Excessive dermal mucin deposition	Serum paraprotein (especially IgG λ)
Nephrogenic systemic fibrosis	Extremities, fingers; symmetric	Frequent, mild (muscle, fascia, lungs)	Fibroblast proliferation, mucin deposition, dermal spindle cell proliferation	After gadolinium exposure in end-stage renal disease
Eosinophilic fasciitis	Extremities, trunk; spares fingers	Rare; low-grade myositis	Dermal and hypodermal sclerosis, normal epidermis, muscle inflammation occasionally	Peripheral blood eosinophilia frequent

Fig. 147.2 Generalized morphea.

topical tacrolimus were most efficacious in treating morphea and appeared to work optimally with inflammatory lesions.²⁸ Ultrasound may be useful for the initial evaluation of lesions in localized scleroderma, especially in distinguishing active from inactive skin lesions.^{34,35}

CONDITIONS THAT MIMIC SCLERODERMA

Scleromyxedema

Scleromyxedema is a rare condition characterized by deposition of mucin in the skin and other organs and is typically associated with the production of a monoclonal IgG protein.³⁶⁻⁴¹ The first documented cases were described at the turn of the 19th century by Dubreuilh and Reitmann as generalized lichen myxedematosus.^{42,43} Another term formerly used was generalized lichenoid papular eruption. The condition was renamed scleromyxedema by Gottron in 1954.⁴⁴ In Gottron's description, the characteristic features consisted of generalized waxy papules with induration and thickening. Other synonyms of scleromyxedema include scleromyxedema of Arndt-Gottron, papular mucinosis, and lichen myxedematosus. Rongioletti and Rebora³⁷ suggested that scleromyxedema should be used to refer to the generalized form of lichen myxedematosus whereas the more localized form of the disease should be termed papular mucinosis.

Although the pathophysiology of scleromyxedema is unknown, fibroblasts appear to have a central role. Serum from patients with scleromyxedema stimulates the *in vitro* proliferation of normal dermal fibroblasts.⁴⁵ Fibroblasts from patients with scleromyxedema appear to synthesize high quantities of hyaluronic acid and subsequently greater amounts of mucin. Furthermore, the heparin sulfate proteoglycan obtained from scleromyxedema papules has been shown to promote fibroblast growth factor activity *in vitro*.

Approximately 83% of patients with this condition have an IgG paraprotein, although there does not appear to be any quantitative relationship between paraprotein levels and clinical manifestations.⁴⁶ In one study of autologous stem cell transplantation in five patients, only two showed eradication of their monoclonal protein, and no association with clinical improvement was noted.⁴⁷

The histology of scleromyxedema is characterized by a triad of mucin deposition, fibroblast proliferation, and fibrosis.⁴⁸ This occurs primarily in the mid and upper reticular dermis (Fig. 147.3). Elastin fibers tend to be decreased in quantity and the epidermis may be thin. Hair follicles may be atrophic. A slight perivascular and superficial lymphocytic and plasmacytic infiltrate may also be present.

The clinical features of scleromyxedema are characterized by widespread symmetric eruption of small waxy papules, which are often linearly and

closely spaced.⁴⁶ They are typically 2 to 3 mm and dome shaped or flat topped and may include the face, neck, distal end of the forearms, and hands, with the palms, scalp, and mucous membranes generally being spared (Fig. 147.4). The lesions are not usually pruritic; however, the Koebner phenomenon may occasionally occur. Leonine facies may also be seen (see Fig. 147.4). The skin stiffness may decrease range of motion in the joints of the hands and larger extremities. Systemic manifestations may result from mucin deposition around vessels in many organs, including the heart and lungs.³⁸ Dysphagia is the most common extracutaneous manifestation and is associated with esophageal dysmotility. Myopathy occurs in approximately 20% of patients.⁴¹ Initial treatment typically includes systemic corticosteroids and melphalan, sometimes in combination with plasmapheresis. Second-line treatments have included isotretinoin and intralesional corticosteroids. Third-line therapies include cyclophosphamide, cyclosporine, thalidomide, autologous stem cell transplantation, intravenous immunoglobulin, and radiation therapy.⁴⁸⁻⁵² A recent report of a patient with severe scleromyxedema failing to respond to initial therapy with prednisone and intravenous immunoglobulin described a partially favorable outcome with high-dose melphalan and autologous stem cell transplantation and, after relapse, a complete response to bortezomib plus dexamethasone.⁵³

The outcome of scleromyxedema is variable. A chronic progressive course is the rule, but spontaneous improvement may occur. Occasionally, severe extracutaneous involvement may result in increased mortality.³⁸

Nephrogenic systemic fibrosis

Nephrogenic systemic fibrosis is a recently described progressive systemic fibrosing disorder that occurs in patients with end-stage renal disease who have undergone magnetic resonance imaging with gadolinium enhancement (see Chapter 170).⁴⁹

Scleredema

Scleredema, or scleredema adultorum of Buschke, is a condition that mimics scleroderma and is characterized by firm, nonpitting edema that typically begins on the neck and spreads to the face, scalp, shoulders, and trunk.⁵⁵ The hands and feet are characteristically spared ("inverse" in comparison to systemic sclerosis). The condition appears to occur in several variants that may be associated with or follow an infection or be associated with diabetes, but some cases have neither association. The condition was first described by Buschke in 1902,⁵⁶ who reported it in a 46-year-old carriage varnisher in whom skin hardening developed on the neck and spread to involve all parts of his body except the hands and thighs. This patient's symptoms arose following an episode of influenza. Graff⁵⁷ subsequently described three variants of scleredema. Type I was considered the classic type identified by Buschke and occurs following an infection or febrile illness, with resolution taking place in months to years. Type II had no preceding febrile illness and no apparent underlying cause and tended to follow a slow, progressive course with an increased risk for the development of paraproteinemia, including multiple myeloma. Type III was termed diabetic scleredema given its association with diabetes.

Skin biopsy specimens from patients with scleredema typically show that the epidermis is not involved.⁵⁵ The dermis tends to be thickened, up to four times normal, with swollen collagen fibers separated by wide spaces in which acid mucopolysaccharides are found.⁵⁸ Although patients with

Fig. 147.3 Histologic features of scleromyxedema showing marked fibroblast infiltration, increased and disorganized collagen deposition, and extensive dermal mucin deposits.

Fig. 147.4 Typical waxy papular deposits in scleromyxedema. (Courtesy Dr. Alan Tyndall.)

scleredema have predominantly dermal involvement, some series have indicated extracutaneous involvement, with mucopolysaccharide staining even within the myocardium in one case.⁵⁹ Tongue involvement causing difficulty swallowing and dysphagia has also been described, as has ocular, bone marrow, and salivary infiltration.⁴⁸ Magnetic resonance imaging may show diffuse thickening of the dermis and subcutaneous tissue with hyperintense signals.⁶⁰

Therapy for scleredema has included trials of thyroid hormone, immunosuppressants, antibiotics, corticosteroids, and physiotherapy, but none has proved to be consistently effective.⁴⁶ Several reports have suggested marked improvement following electron beam therapy.⁶¹ A recent report described complete remission of multiple myeloma-associated scleredema after bortezomib-based treatment.⁶² A case of poststreptococcal scleredema was reported to successfully respond to intravenous immunoglobulin.⁶³

Eosinophilic fasciitis

Eosinophilic fasciitis (EF) was first described by Shulman in 1974, who reported two patients with scleroderma-like skin changes and induration of subcutaneous tissue of the extremities associated with peripheral eosinophilia.⁶⁴

Deep dermal biopsy specimens showed evidence of diffuse fasciitis, and the condition was later termed EF.^{65,66} Other terms for this syndrome include Shulman disease and diffuse fasciitis with eosinophilia. Similar conditions resulting from the ingestion of toxic contaminants in two epidemics have also been reported, one termed toxic oil syndrome in Spain and the other eosinophilia-myalgia syndrome in the United States.⁶⁷⁻⁷⁰ The conditions were also characterized by eosinophilia, variable skin fibrosis, and pathologic evidence of fasciitis. In some cases these conditions resulted in severe multisystem involvement and a high mortality rate, which is uncommon with EF.

The histopathologic features of EF include dermal and hypodermal sclerosis associated with fibrotic thickening of the subcutaneous adipose lobular septa, superficial fascia, and perimysium.⁷¹ The epidermis is typically normal. Mild inflammation may be present in the muscle layer. An antecedent history of vigorous exercise or trauma may occur in as many as 50% of patients. Toxic exposure other than aniline-denatured rapeseed oil and L-tryptophan (in the other conditions mentioned) has not been found, although several cases have been associated with positive serologic findings for *Borrelia burgdorferi*; spirochetal organisms have been identified in some patients with EF.^{72,73}

The clinical manifestations of EF often evolve in three stages, the first being pitting and edema; the second being “peau d’orange” and induration, with the arms and legs most commonly affected; and the third consisting of development of the “groove sign,” a dimpled appearance of the medial aspect of the upper part of the arm with elevation where the collapsed branchial vein leaves an indentation (Fig. 147.5).^{74,75} Involvement of the feet and hands is uncommon. Low-grade myositis may be present, although the serum creatinine kinase level is usually normal.⁷⁶ Periarticular involvement may result in flexion contractures and significant functional disability, as well as in peripheral nerve compression, especially carpal tunnel syndrome. True sclerodactyly and nail fold capillary abnormalities do not occur.

Laboratory features include peripheral eosinophilia, which may be present in up to 80% of cases. Laboratory findings include polyclonal hypergammaglobulinemia and increased acute-phase reactant levels such as the erythrocyte sedimentation rate and C-reactive protein.

EF has been associated with malignancy, especially hematologic malignancies, including leukemia and aplastic anemia.⁷⁷⁻⁸²

Published series suggest that corticosteroids appear to be the first line of treatment of EF. Other therapies have included antihistamines, D-penicillamine, antimalarials, and cytotoxic agents. Endo and colleagues⁸³ recently reviewed a large number of EF cases and found that clinical variables associated with a poorer outcome (defined as refractory disease or residual skin fibrosis despite prolonged treatment) included young age, presence of morphea-like skin lesions, and trunk involvement. An important component of treatment is physical therapy to minimize the sequelae of flexion contractions and their subsequent disability. Lebeaux and

Fig. 147.5 The “groove sign” of eosinophilic fasciitis.

colleagues⁸⁴ reviewed treatment outcomes in 34 patients with biopsy-proven EF. Pulse methylprednisolone at initiation of treatment (500 to 1000 mg daily for 3 consecutive days) was associated with better outcomes and a lower need for immunosuppressive drugs.

Chronic graft-versus-host disease

GVHD is the most common serious complication of allogeneic hematopoietic stem cell transplantation. It comes in two forms: acute and chronic. Acute GVHD induces a variety of clinical conditions, including dermal, gastrointestinal, and pulmonary complications, and occurs in approximately 30% to 50% of sibling donor recipients and a higher fraction of unrelated donor recipients.⁸⁵ The pathogenesis of GVHD is multifactorial, but the currently accepted paradigm suggests that donor T cells recognize alloantigenic host peptides and are activated, expand, and migrate to lymphoid organs, where further peripheral expansion occurs. This triggers the cytokine and cytolytic injury manifested as GVHD.

Chronic GVHD (cGVHD) occurs with a high likelihood after acute GVHD. cGVHD is a distinct syndrome but shares overlapping features with acute GVHD, such as an erythematous skin eruption, nausea, vomiting, diarrhea, and cholestatic liver disease. Distinctive or differentiating features of cGVHD include sicca syndrome, obstructive bronchiolitis, and lichenoid or sclerotic skin changes, which bear the closest similarity to scleroderma.⁸⁶ Skin manifestations may also include telangiectases, ulcers, and joint contractures, but the Raynaud phenomenon is not seen. Treatment of cGVHD requires extended-duration immunosuppressive therapy, infection prophylaxis, nutritional management, and physical therapy. Corticosteroids remain the mainstay of therapy, but often they are not fully effective, and long-term use leads to multiple complications. Other agents, including calcineurin inhibitors, sirolimus, mycophenolate mofetil, thalidomide, pentostatin, and extracorporeal photopheresis, have all produced responses in phase 2 trials, but no agent has been shown to be superior to corticosteroids in randomized trials.⁸⁷ Because tumor necrosis factor- α (TNF- α) has been implicated in the pathophysiology of GVHD, TNF inhibition with infliximab has been used with some efficacy in steroid-refractory GVHD involving the gastrointestinal tract in small studies.⁸⁸ Tyrosine kinase inhibitors such as imatinib may have potential efficacy in steroid-refractory cGVHD.⁸⁹ Because T cells are thought to play a central role as effectors of cGVHD, there has been considerable interest in strategies to prevent cGVHD by using *ex vivo* T cell-depleted allogeneic bone marrow transplantation, which appears to be associated with lower rates of cGVHD. Similarly, *in vivo* T-cell depletion with alemtuzumab or antithymocyte globulin has been reported to produce low rates of cGVHD.⁸⁷

Clinical features, classification, and epidemiology of inflammatory muscle disease

■ CHESTER V. ODDIS ■ DANA P. ASCHERMAN

- Chronic inflammation of striated muscle (myositis) is associated with characteristic cutaneous features (rash of dermatomyositis) and a variety of systemic complications.
- The cellular and humoral immunologic features of inflammatory muscle disease include serum autoantibodies in association with clinical syndromes, with myositis being a major manifestation.
- Painless symmetric proximal muscle weakness with or without rash typically is present.
- Serum muscle enzymes are increased, most notably creatine kinase.
- Electromyographic findings are normal, and muscle biopsy demonstrates inflammatory infiltrates.
- Other organ systems can also be involved, including the lung, heart, gastrointestinal tract, and joints.
- Dermatomyositis is associated with malignancy in the middle-aged and elderly population.

EPIDEMIOLOGY

Classification criteria

Many classification systems have been proposed for polymyositis-dermatomyositis (PM-DM, referred to collectively as myositis or the idiopathic inflammatory myopathies [IIMs] in the remainder of this chapter).^{1,2} The Bohan and Peter criteria have been used most frequently (Box 148.1), with a sensitivity of 70% for definite myositis and a specificity of 93% in discriminating patients with myositis from those with systemic lupus erythematosus (SLE) or systemic sclerosis (SSc).³ Increasing reports of amyopathic dermatomyositis (ADM—rash of DM without muscle weakness), coupled with the detection of several autoantibodies and imaging techniques, have spearheaded an international effort to update the classification criteria for myositis.

Association with other disorders

PM-DM occurs in overlap with SSc more frequently than with any other connective tissue disease and is often associated with one of several serum autoantibodies such as anti-U1-RNP, anti-PM-Scl, or anti-U3-RNP.⁴ In one study, IIM overlapped with another connective tissue disease in the majority of patients (60%) when clinical and serologic features contributed to the classification.⁵ Myositis has also been described in association with other conditions.⁶

Incidence and prevalence by age, race, and sex

The overall incidence of IIM ranges from 2 to 10 new cases per million persons at risk per year, but there is a trend toward increasing incidence over time, probably because of increased physician awareness. A report on the prevalence of inclusion body myositis (IBM) in Western Australia recorded the highest reported figure to date: 14.9 per million, which increased to 51.3 cases per million in those older than 50 years.⁷

Although inflammatory myopathy can occur at any age, the observed pattern of occurrence includes peaks in both childhood and adulthood, with a paucity of patients having an onset in the adolescent or young adult years. As expected, the mean age at the onset of myositis is increased when associated with malignancy. The overall female-to-male incidence ratio is 2.5:1, lower (nearly 1:1) in childhood disease and with malignancy, but very high (10:1) when in overlap with another coexisting connective tissue disease. IIM has a 3:1 to 4:1 black-to-white ratio of incidence and a younger adult-onset peak in blacks.

Environmental factors

The prevalence of IIM in Europe increases significantly (sevenfold) from the north (Iceland) to the south (Greece), which could have either an environmental or a genetic explanation.⁸ Spatial clustering has been reported,⁹ and investigators have noted that expression of anti-Mi-2 autoantibodies in women is associated with the intensity of ultraviolet (UV) radiation,¹⁰ thus suggesting that UV radiation may modulate the clinical and immunologic expression of autoimmune disease in patients with myositis.

Onset of disease is more frequent in the winter and spring months, especially in childhood cases, and uncontrolled observations have noted a history of antecedent respiratory or gastrointestinal complaints, treated with antibiotics, preceding the onset of juvenile dermatomyositis (JDM).¹¹ An infectious trigger is supported by finding serum antibodies to Coxsackie B viruses more frequently in JDM than in juvenile controls with rheumatoid arthritis. Seasonal birth patterns appear to be more common in juvenile myositis than in adult IIM, perhaps suggesting a greater influence of perinatal exposure in childhood myositis.¹² Disease relapses were noted most frequently during the summer months, possibly precipitated by infection or sun exposure.¹³ DM and PM have occurred in patients infected with human immunodeficiency virus, and myositis occurs more frequently in those with chronic graft-versus-host disease (GVHD), thus suggesting that skeletal muscle may be a target in some patients with GVHD.^{14,15}

Genetic factors

The occurrence of IIM in monozygotic twins and first-degree relatives of affected individuals supports a genetic predisposition in some families. Other autoimmune diseases occur four times more frequently in first-degree relatives of patients with IIM (21.9%) than in first-degree relatives of control probands (4.9%),¹⁶ and the same principle applies to JDM.¹⁷

Recent large U.K.- and U.S.-based efforts to study white IIM patients have uncovered significant associations of genotype with clinical and serologic profiles in myositis.¹⁸⁻²⁰ These findings emphasize the importance of HLA haplotypes and peptide-binding motifs in discriminating between IIM subsets. Alleles of the 8.1 ancestral haplotype (HLA-DRB1*03-DQA1*05-DQB1*02), for example, are important risk factors for the development of myositis in antisynthetase antibody-positive patients, as well as in those producing anti-La, anti-PM/Scl, and anti-Ro autoantibodies.²⁰ Although anti-Jo-1 and anti-PM-Scl antibody-positive patients share the 8.1 ancestral haplotype, analysis of the HLA-DPB1 region has shown that DPB1*0101 is associated with anti-Jo-1 positivity but not with the formation of anti-PM-Scl antibodies.²¹

JDM has been associated with HLA-DQA1*0501, and the closely linked DRB1*0301 allele is also a risk factor for IIM in white individuals. Genes regulating cytokines and their receptors, including PTPN22, interleukin-1, and tumor necrosis factor- α , also appear to play a role in the development and course of both childhood and adult-onset myositis.^{22,23}

BOX 148.1 BOHAN AND PETER CRITERIA FOR THE DIAGNOSIS OF POLYMYOSITIS AND DERMATOMYOSITIS

Individual criteria
1. Symmetric proximal muscle weakness
2. Muscle biopsy evidence of myositis
3. Increase in serum skeletal muscle enzymes
4. Characteristic electromyographic pattern
5. Typical rash of dermatomyositis
Diagnostic criteria
Polymyositis:
Definite: all of 1 to 4
Probable: any 3 of 1 to 4
Possible: any 2 of 1 to 4
Dermatomyositis:
Definite: 5 plus any 3 of 1 to 4
Probable: 5 plus any 2 of 1 to 4
Possible: 5 plus any 1 of 1 to 4

Modified from Bohan A, Peter JB. Polymyositis and dermatomyositis. *N Engl J Med* 1975;292:344-7, 403-7.

TABLE 148.1 Types and frequencies of initial clinical syndromes in patients with polymyositis-dermatomyositis

Syndrome	Estimated frequency (%)
Dermatomyositis rash alone; extremity edema	<1
Painless proximal weakness (over 3-6 mo)	55
Acute or subacute proximal pain and weakness (over weeks to 2 mo)	30
Insidious proximal and distal weakness (over 1-10 yr)	10
Proximal myalgia alone	5

CLINICAL FEATURES

The initial features of myositis vary considerably from patient to patient (Table 148.1); most common is insidious, progressive, and painless symmetric proximal muscle weakness arising over the course of 3 to 6 months. Some patients, especially children with DM, have a more acute onset of disease, with fever, muscle pain, and weakness developing over the course of several weeks. In contrast, a subset of patients exhibit slowly evolving weakness over the course of 1 to 10 years that involves atrophy of the quadriceps muscles or forearms (or both), weakness of the pelvic girdle and distal extremity muscles, and pathologic features of IBM noted on muscle biopsy specimens.

Pharyngeal muscle weakness may contribute to hoarseness, dysphagia, nasal regurgitation of liquids, or aspiration pneumonia. Ventilatory muscle weakness may contribute to dyspnea, although interstitial lung disease (ILD) is a more common cause of pulmonary dysfunction.

Distinctive cutaneous manifestations (see later) may occur before muscle weakness is detected. In patients with a DM rash as the sole or predominant manifestation for more than 2 years, the terms amyopathic or clinically amyopathic DM or hypomyopathic DM are used. These patients remain at risk for ILD, malignancy, or even delayed-onset full-blown DM.²⁴

The initial clinical manifestations often “cluster” together and hence result in distinct syndromes. For example, patients with anti-aminoacyl-tRNA synthetase autoantibodies such as anti-Jo-1 antibody have a constellation of findings in addition to myositis, including fever, Raynaud phenomenon, mechanic’s hands, polyarthritis, and ILD. When myositis overlaps with SSc, Raynaud phenomenon, puffy fingers, sclerodactyly, and distal esophageal (smooth muscle) hypomotility may be prominent clinical features. Myositis overlapping with SLE may include photosensitivity, malar rash, alopecia, polyarthralgia, pleurisy, and leukopenia.

Constitutional

Fatigue is a prominent complaint in patients with IIM, and fever is observed in JDM and adults with antisynthetase syndrome. Weight loss may occur as

TABLE 148.2

Key to muscle grading

Function of the muscle	Grade*		
No contraction felt in the muscle	0	0	0
Tendon becomes prominent or feeble contraction felt in the muscle, but no visible movement of the part	Trace	1	T
Movement in the horizontal plane			
Moves through partial range of motion	Poor–	2–	1
Moves through complete range of motion	Poor	2	2
Antigravity position			
Moves through partial range of motion	Poor+	2+	3
Gradual release from the test position	Fair–	3–	4
Holds the test position (no added pressure)	Fair	3	5
Holds the test position against slight pressure	Fair+	3+	6
Holds the test position against slight to moderate pressure	Good–	4–	7
Holds the test position against moderate pressure	Good	4	8
Holds the test position against moderate to strong pressure	Good+	4+	9
Holds the test position against strong pressure	Normal	5	10

*Three different scoring systems for grading muscle weakness are noted. Adapted from Kendall FP, McCreary EK. *Muscle testing and function*. 4th ed. Baltimore: Williams & Wilkins; 1993.

in any systemic inflammatory disorder, but if persistent and severe, associated malignancy should be considered. Additional factors contributing to weight loss include poor caloric intake associated with pharyngeal dysfunction or esophageal dysmotility. Obstructive sleep apnea is common in patients with IIM and perhaps contributes to their persistent fatigue.²⁵

Skeletal muscle

The onset of muscle weakness is typically insidious, bilateral, symmetric, and painless, with involvement of proximal more than distal muscles. An exception is IBM, in which asymmetric distal weakness and atrophy are as prominent as the proximal muscle findings. In PM-DM, the lower extremity (pelvic girdle) is often affected initially and results in difficulty climbing stairs or arising from a chair or toilet seat. Involvement of the hip flexors correlates with impaired walking speed in juvenile patients with myositis, and impaired strength in specific lower extremity muscle groups predicts gait limitations in children.²⁶

Upper extremity (shoulder girdle) symptoms often follow, with patients experiencing difficulty raising their arms overhead or combing their hair. Neck flexor weakness is manifested by an inability to raise the head from a pillow. Muscle pain may occur and is more common in DM, particularly with exercise. Proximal dysphagia with nasal regurgitation of liquids and pulmonary aspiration reflects the involvement of pharyngeal striated muscle and is a poor prognostic sign seen with severe disease. Pharyngeal weakness also results in hoarseness or dysphonia, which gives the voice a nasal quality. Ocular or facial muscle weakness is very uncommon in PM-DM, and their presence should therefore prompt consideration of another diagnosis.

Physical examination confirms weakness of individual muscles or groups of muscles (Table 148.2). Although the severity of weakness should be assessed serially and recorded with one of the scales in Table 148.2, functional measures should also be considered. In juvenile myositis, the Childhood Myositis Assessment Scale is both reliable and valid for assessing physical function, muscle strength, and endurance.²⁷ Other, more quantitative means of measuring muscle strength are time-consuming and include the use of expensive equipment, but simpler methods using hand-held dynamometers have been validated in other neuromuscular diseases.

Muscle atrophy and joint contractures are sequelae of the damage caused by disease; they are therefore late findings in chronic PM-DM, in contrast to IBM, in which muscle atrophy is more common at initial evaluation.

Skin

DM has a characteristic rash that may precede, develop simultaneously with, or follow the muscle symptoms. Gottron papules and a heliotrope rash

are considered pathognomonic cutaneous features of DM. Gottron papules (Fig. 148.1) are scaly, erythematous, or violaceous papules and plaques located over bony prominences, particularly the metacarpophalangeal and proximal and distal interphalangeal joints of the hands. The Gottron sign (Fig. 148.2) is a macular erythema that occurs in the same distribution and over other extensor areas such as the elbows, knees, and ankles. Later in the course of disease, the affected skin lesions may become shiny, atrophic, and hypopigmented with telangiectases. Seen in less than 50% of patients with DM, heliotrope rash is purplish in color, may be edematous or scaling in nature, and is located in the periorbital area, especially over the upper eyelids (Fig. 148.3). Cutaneous photosensitivity with facial erythema (Fig. 148.4) or a “V” sign over the anterior aspect of the chest (Fig. 148.5) may also be seen in DM. Pruritus is common and underrecognized,²⁸ and its presence differentiates DM from SLE, in which pruritus is uncommon.

The “shawl” sign refers to a rash located over the nape of the neck, upper part of the back, and across both shoulders (Fig. 148.6). Located on the lateral surface of the thighs and hips, the “holster” sign is a feature of DM (Fig. 148.7). Cuticular hypertrophy and hemorrhage with periungual erythema, telangiectases, infarcts, and capillary dilation are seen in both DM and myositis in overlap with other connective tissue diseases (Fig. 148.8). Cracking or fissuring of the lateral and palmar digital skin pads is termed “mechanic’s hands” (Fig. 148.9) and most frequently occurs in patients with PM who have anti-tRNA synthetase or anti-PM-Scl autoantibodies.²⁹ Patients with autoantibodies targeting melanoma differentiation–associated gene 5 (MDA5), also termed clinically amyopathic DM-140 (CADM-140), have

recently been shown to have cutaneous ulcerations, palmar papules, or both as features of severe vasculopathy.³⁰

Other cutaneous findings seen in patients with IIM are listed in Box 148.2.³¹

Calcinosis

Soft tissue calcification, which can be disabling, occurs most commonly in chronic, childhood-onset DM.³² Calcinosis is typically seen in the setting of chronic, active disease or with a delay in initial treatment. Autoantibodies to a newly described 140-kDa antigen have been found in JDM with a clinical phenotype that includes calcinosis.³³ The pathogenesis of calcinosis is multifactorial but may be related to the cytokines found in calcinotic fluid in JDM.³⁴ Because of the disorganized nature of the calcifications in JDM and their different structure and composition from bone, it has been suggested that they do not form from an osteogenic pathway.³⁵

Calcinosis may be intracutaneous, subcutaneous, fascial, or intramuscular in location, with a predilection for sites of repeated microtrauma (elbows, knees, flexor surfaces of the fingers, and buttocks). Complications include the formation of an exoskeleton and cutaneous ulceration with secondary infection and joint contractures. Medical therapy has been disappointing.

Joints

Polyarthralgia and polyarthritis, if they occur, appear early in the course of disease. The distribution is rheumatoid-like, and the symptoms are relatively mild. Joint findings are more common with overlap and antisynthetase syndromes, in which case they can be chronic and deforming³⁶ with instability of the interphalangeal thumb joint (“floppy thumb” sign), erosions,³⁷ and periarticular calcifications³⁸ (Fig. 148.10).

Fig. 148.1 Gottron papules. This erythematous, scaling rash over the knuckles and dorsum of the hand is a common early sign of dermatomyositis. It can be distinguished from the rash of systemic lupus erythematosus, which usually affects the phalanges and spares the knuckles.

Fig. 148.2 Gottron sign. Scaling and macular erythema are evident over the extensor surface of the elbow in a patient with dermatomyositis.

Fig. 148.3 (a) Heliotrope rash of dermatomyositis demonstrating both erythema and diffuse periorbital edema. (b) As opposed to the periorbital edema in (a), this patient has more erythema and scaling with less swelling.

Fig. 148.4 Facial rash of dermatomyositis. Note the malarlike rash of dermatomyositis, which also involves the nasolabial area (an area often spared in systemic lupus erythematosus). Patchy involvement of the forehead and chin is also present.

Fig. 148.5 V-neck rash in a patient with dermatomyositis demonstrating its photosensitive nature over the anterior aspect of the chest.

Fig. 148.6 "Shawl" sign in a patient with dermatomyositis featuring an erythematous rash across the upper part of the back and extending onto the neck in the distribution of where a shawl is worn.

Fig. 148.7 "Holster" sign in a patient with dermatomyositis consisting of erythema on the lateral aspect of the thigh adjacent to hand of the same patient with Gottron erythema.

Fig. 148.8 Cuticular overgrowth with periungual erythema and capillary dilatation in a patient with dermatomyositis.

Fig. 148.9 "Mechanic's hands." Note the erythema, hyperkeratotic changes and cracking of the skin on the lateral aspects of the fingers in this patient with anti-Jo-1 autoantibody.

Lung

The lung is the most common internal organ affected in PM-DM. Dyspnea in patients with myositis has many potential causes (Box 148.3), including parenchymal and nonparenchymal problems such as ventilatory (diaphragmatic and intercostal) muscle weakness or cardiac dysfunction (see the next section). However, ventilatory muscle weakness leading to respiratory failure or significant dyspnea is uncommon and occurs in less than 5% of patients.⁴⁰

The frequency of “intrinsic” pulmonary involvement has been reviewed in many studies.⁴¹ In 70 patients with ILD and either PM or DM,⁴² more than 80% who underwent lung biopsy were found to have nonspecific interstitial pneumonia (NSIP), which was generally responsive to therapy with good survival. A retrospective study from France reported that a quarter of consecutive patients with IIM had ILD, 25% of whom subsequently deteriorated.⁴³ A retrospective analysis of 151 patients with PM and DM from China showed that ILD developed in a fifth.⁴⁴ Older age at onset, the presence of anti-Jo-1 autoantibodies, and joint symptoms were associated with ILD. In this cohort, poor survival with ILD correlated with male

gender, a Hamman-Rich–like manifestation, and a clinical diagnosis of acute interstitial pneumonitis. A prospective study from Sweden identified 11 of 17 (65%) new PM and DM patients over a 2.5-year period with lung disease, 18% of whom had subclinical ILD.⁴⁵ In an enriched population of 90 anti-Jo-1 antibody–positive patients, 77 (86%) met the criteria for ILD.⁴⁶ In contrast to adult PM-DM, pulmonary disease in JDM is rare.^{47,48}

In general, the presence of “ground-glass” opacities on high-resolution computed tomography (HRCT) implies a treatment-responsive condition, whereas “honeycombing” and traction bronchiectasis correspond to fibrosis that is less amenable to immunosuppressive therapy.⁴⁹

Pulmonary function testing (PFT) reveals restrictive physiology with reduced lung volumes (e.g., total lung capacity and forced vital capacity) and a parallel decrease in the diffusion capacity for carbon monoxide. Although HRCT and PFT provide useful information, histopathologic classification may be the most critical determinant of the course of disease. NSIP and the organizing pneumonias (see Box 148.3) represent a more favorable histopathology, whereas usual interstitial pneumonia and diffuse alveolar damage (DAD) portend a more ominous course.⁴⁰ DM-associated ILD may be more commonly associated with DAD, thus indicating that pulmonary histologic differences and HRCT findings may further distinguish PM from DM.^{50,51} In addition, the concomitant finding of anti-Ro/SSA in patients with antisynthetase autoantibodies may be associated with more severe and progressive ILD.^{52,53}

Beyond these issues, parenchymal lung involvement may be associated with other less commonly considered complications. “Secondary” pulmonary arterial hypertension can also develop in patients with progressive ILD as a result of hypoxemia-induced pulmonary vasoconstriction, although “primary” pulmonary hypertension secondary to underlying pulmonary vasculopathy/vasculitis should be considered as well. Diffuse alveolar hemorrhage with pulmonary capillaritis is uncommon but can be lethal. Pneumomediastinum, on the other hand, is being reported increasingly and may be associated with rapidly progressive ILD in the setting of ADM.³⁹

BOX 148.2 CUTANEOUS FEATURES OF THE IDIOPATHIC INFLAMMATORY MYOPATHIES

Pathognomonic signs in dermatomyositis

Gottron papules (60% to 80% of patients)
Heliotrope rash (50% or less)

Less specific signs in dermatomyositis

Gottron sign
Photosensitivity
“V” sign
Pruritic scalp involvement
“Shawl” sign
“Holster” sign
Nail-fold capillary changes with cuticular overgrowth

Other skin findings in polymyositis or dermatomyositis³¹

Calcinosis
“Mechanic’s hands”
Skin ulcers with tender palmar papules³⁰
Panniculitis
“Linear extensor erythema”
Pityriasis rubra pilaris (palmar plantar hyperkeratoses)
Facial seborrhea
Papular mucinosis (scleromyxedema)
Acquired ichthyosis
Vesiculobullous disorders
Urticarial (lymphocytic) vasculitis
Acquired lipodystrophy and acanthosis nigricans
Vitiligo
Multifocal lipotrophy
Poikiloderma

BOX 148.3 CAUSES OF DYSPNEA IN PATIENTS WITH IDIOPATHIC INFLAMMATORY MYOPATHY

Nonpulmonary etiology

Respiratory muscle weakness
Cardiac involvement

Pulmonary etiology

Interstitial lung disease
■ Nonspecific interstitial pneumonitis (NSIP)
■ Usual interstitial pneumonitis (UIP)
■ Diffuse alveolar damage (DAD)
■ Organizing pneumonias (cryptogenic organizing pneumonia [COP])
Pulmonary hypertension
Alveolar hemorrhage
Pneumomediastinum³⁹
Infection (with or without aspiration)
Drug induced (e.g., methotrexate)

Fig. 148.10 Deforming arthropathy of polymyositis. (a) Rheumatoid-like deformities of the hand in a patient with anti-Jo-1 autoantibody. (b) Radiograph of this patient's hand showing numerous subluxations but minimal bony erosive changes.

Heart

Subclinical heart involvement is common in PM-DM.⁵⁴ The most frequent finding is a rhythm disturbance, and complete atrioventricular block has been reported.⁵⁵ More ominous complications such as congestive heart failure (caused by myocarditis or myocardial fibrosis), pericardial tamponade, and restrictive cardiomyopathy are very unusual.^{56,57} Affected patients complain of palpitations or tachycardia, and other features of congestive heart failure are noted on physical examination. Myocardial infarction may rarely result from coronary vasospasm, accelerated atherosclerosis associated with prolonged glucocorticoid use, or coronary arteritis.

Gastrointestinal tract

The pharyngeal musculature is striated and a potential target for myositis. The voice may become nasal in quality (dysphonia), and oropharyngeal swallowing dysfunction (upper dysphagia) with difficulty in the initiation of deglutition or nasal regurgitation of liquids may result. If severe, aspiration of oral contents leads to chemical pneumonitis with secondary bacterial infection.

Esophageal dysmotility is seen in both overlap disorders and pure PM and DM. Patients note a retrosternal “sticking” sensation on swallowing bread or meat and heartburn with esophageal body and gastroesophageal sphincter involvement, respectively. Postprandial symptoms of pain, bloating, distention (pseudoobstruction), or watery diarrhea with weight loss (malabsorption syndrome) indicate small bowel involvement. “Total gut failure” secondary to an atonic bowel and pneumatosis cystoides intestinalis have also been reported.⁵⁸

Gastrointestinal mucosal ulceration and hemorrhage as a result of vasculitis can occur in JDM. Active and quiescent forms of myositis are increasingly being reported in conjunction with other autoimmune gastrointestinal disorders, including inflammatory bowel disease, primary biliary cirrhosis, sclerosing cholangitis, and celiac disease, in adults as well as children.⁵⁹⁻⁶²

Peripheral vascular system

Raynaud phenomenon is observed in all IIM subsets except for malignancy-associated myositis. Systemic vasculitis is common in JDM but uncommon in adults. The inflammatory vascular lesions of DM include tender dermal and subcutaneous nodules, periungual infarcts, and digital ulcerations.

Kidney

Renal disease is considered unusual in myositis. Generalized edema and rhabdomyolysis with renal failure can be seen in IIM (particularly DM) but do not necessarily indicate primary renal disease.^{63,64} The presence of primary renal disease should prompt a search for an associated connective tissue disease or other associated condition.

DIFFERENTIAL DIAGNOSIS

Noninflammatory myopathies

The differential diagnosis of adult PM-DM is broad and includes numerous conditions capable of affecting skeletal muscle (Table 148.3). The history, physical examination, and differences in laboratory test results serve as the primary method of distinguishing these conditions. Although muscle biopsy may not be diagnostic in some patients with inflammatory myopathy, it is an essential part of the evaluation and should include immunocytochemical and enzyme staining, as well as electron microscopy in selected cases.

Primary neurologic diseases mimicking myopathy include the spinal muscular atrophies, a group of autosomal recessive disorders leading to slowly progressive degeneration of spinal anterior horn cells, and amyotrophic lateral sclerosis, a disease that results in more rapid degeneration of both lower and upper motor neurons (causing bulbar or pseudobulbar palsy). Myasthenia gravis is a disorder of the neuromuscular junction in which weakness often affects the extraocular and bulbar muscles and

TABLE 148.3
Differential diagnosis of muscle weakness

General type	Subtypes/examples
Denervating conditions	Spinal muscular atrophy,* amyotrophic lateral sclerosis*
Neuromuscular junction disorders	Eaton-Lambert syndrome,* myasthenia gravis*
Genetic muscular dystrophies	Duchenne facioscapulohumeral, limb-girdle,* Becker, Emery-Dreifuss types,* distal, ocular
Myotonic diseases	Dystrophia myotonica,* myotonia congenita
Congenital myopathies	Nemaline, mitochondrial, centronuclear, central core
Glycogen storage diseases	Adult-onset acid maltase deficiency,* McArdle disease
Lipid storage myopathies	Carnitine deficiency,* carnitine palmitoyltransferase deficiency*
Periodic paralyses	
Myositis ossificans*	Generalized and local
Endocrine myopathies*	Hypothyroidism, hyperthyroidism, acromegaly, Cushing disease, Addison disease, hyperparathyroidism, hypoparathyroidism, vitamin D deficiency myopathy, hypokalemia, hypocalcemia
Metabolic myopathies*	Uremia, hepatic failure
Toxic myopathies*	Acute and chronic alcoholism; drugs, including penicillamine,* clofibrate,* chloroquine, emetine
Nutritional myopathies	Vitamin E deficiency,* malabsorption*
Carcinomatous neuromyopathy*	Carcinomatous cachexia
Acute rhabdomyolysis*	
Proximal neuropathies	Guillain-Barré syndrome,* acute intermittent porphyria,* diabetic lower limb chronic plexopathies,* chronic autoimmune polyneuropathy
Microembolization by atheroma or carcinoma	
Polymyalgia rheumatica*	
Other collagen vascular diseases	Rheumatoid arthritis, scleroderma, systemic lupus erythematosus, polyarteritis nodosa
Infections	Acute viral, including influenza, mononucleosis, coxsackievirus, and rubella and rubella vaccination; <i>Rickettsia</i> ; acute bacterial, including typhoid
Parasites	<i>Toxoplasma</i> , <i>Trichinella</i> , <i>Schistosoma</i> , <i>Cysticercus</i> , <i>Sarcosporidia</i>
Septic myositis	<i>Staphylococcus</i> , <i>Streptococcus</i> , <i>Clostridium perfringens</i> (<i>welchii</i>), and leprosy

*Conditions most commonly confused with muscle weakness.

becomes worse with prolonged or repetitive use. A similar pattern of activity-increased weakness is found in Eaton-Lambert syndrome. These conditions are distinguishable from IIM on the basis of characteristic electromyographic (EMG) patterns and the absence of increased serum muscle enzymes.

The congenital myopathies, including various forms of muscular dystrophy and nemaline myopathy, are hereditary conditions with an onset of symptoms primarily in infancy or childhood but occasionally in adulthood. Some congenital myopathies such as dysferlinopathies are difficult to differentiate from inflammatory myopathy; however, despite manifesting inflammation on muscle biopsy specimens in a pattern similar to PM (without accompanying major histocompatibility complex [MHC] class I upregulation), they are distinguished by a slowly progressive downhill course that is generally unaffected by glucocorticoid or immunosuppressive treatment.⁶⁵ Confounding this issue, some recently described limb-girdle muscular dystrophies not only demonstrate inflammation but also display steroid responsiveness, thus making them difficult to distinguish from PM.^{66,67} In such cases, gene expression profiles from muscle biopsy specimens may provide important differentiating information.⁶⁸ A comprehensive review of the diagnostic uncertainty associated with the inflammatory myopathies and consideration of other myopathic syndromes has been published.⁶⁹

Metabolic and mitochondrial myopathies that can be confused with IIM occur because of genetic defects that result in abnormal energy metabolism.⁷⁰⁻⁷² In particular, acid maltase deficiency (Pompe disease) can mimic PM. Increasingly recognized forms of weakness that develop in seriously ill patients include both “critical illness polyneuropathy” and “acute myopathy of intensive care.” Other causes of noninflammatory proximal myopathy include vitamin D deficiency, calciphylaxis, adrenal insufficiency, hypophosphatemia, hypothyroidism, hyperthyroidism, carcinomatous neuropathy, and exposure to certain toxic substances.

Other inflammatory myopathies

Viral (e.g., human immunodeficiency, influenza), bacterial (e.g., staphylococcal), and parasitic (e.g., trichinosis, toxoplasmosis) infections can mimic IIM. Giant cell myositis is rare but can be encountered in sarcoidosis. Cutaneous sarcoidosis may resemble DM, whereas sarcoid myositis can mimic PM.⁷³

Focal or more generalized (PM or perimyositis) eosinophilic myositis syndromes should be distinguished from eosinophilic fasciitis and eosinophilia-myalgia syndrome, which rarely cause myofiber necrosis, muscle weakness, or increased creatine kinase (CK).

Statin-induced, immune-mediated necrotizing myopathy (IMNM) is a newly described entity characterized by markedly elevated CK levels and variable degrees of proximal muscle weakness that persist or progress even after discontinuation of the offending agent.^{74,75} Although this subclass of inflammatory myopathy involves myofiber necrosis, regeneration, and macrophagic (rather than lymphocytic) infiltration, the association with anti-hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase (HMGCR) antibodies and response to immunomodulatory therapy distinguish IMNM from various dystrophies that share overlapping histopathologic features.^{74,76} Because some forms of paraneoplastic myopathy also yield predominant myofiber necrosis,⁷⁷ assessment for a history of statin exposure and detection of anti-HMGCR antibodies are critical determinants guiding the diagnostic evaluation, as well as therapeutic intervention.

Malignancy and myositis

Several reports strongly support an increased risk for cancer in patients with PM-DM,⁷⁸⁻⁸⁴ with the strongest association occurring in those with DM. Standardized incidence ratios are 3.0 to 12.6 in patients with DM.⁸⁰⁻⁸² In a pooled analysis of published national data from Sweden, Denmark, and Finland, 618 patients with DM were identified, 198 of whom had cancer.⁸¹ The strongest associations were with ovarian, lung, pancreatic, stomach, and colorectal cancer, as well as with non-Hodgkin lymphoma. A lower, but statistically significant increase in cancer rates was seen with PM.

The overall risk for cancer is greatest in the first 3 years after the diagnosis of myositis,⁸⁵ but an increased risk for malignancy persists through all years of follow-up, thus emphasizing the importance of continued surveillance.^{78,81} Although older individuals with DM are at greater risk, the likelihood of malignancy is increased even in DM patients younger than 45 years.⁸¹

Clinical and histologic features that may predict the presence of a malignancy in a patient with DM include an elevated erythrocyte sedimentation rate, epidermal necrosis, cutaneous leukocytoclastic vasculitis, and

ADM.^{84,86-89} The presence of either pulmonary fibrosis, a clinically confirmed connective tissue disease, or myositis-associated or myositis-specific serum autoantibodies decreases the likelihood of cancer,^{80,90,91} but malignancy in the setting of antisynthetase syndrome and ILD has been reported.⁹²

Given the distribution of tumors just noted, an age- and gender-appropriate evaluation for malignancy should include chest, abdominal, and pelvic computed tomography scans, along with fecal occult blood testing, mammography and pelvic examination in women, and prostate examination in men. Because the increased risk for malignant disease persists long after the development of DM, careful patient follow-up should extend for a number of years.⁸¹ To predict the occurrence of malignancy, one group of investigators developed an artificial neural network method using detailed information from 62 patients with IIM; although a combination of eight variables yielded a global predictive value close to 93% with a sensitivity of 98% and specificity of 91%, this model has not yet been validated.⁹¹

INVESTIGATIONS

General concepts

Standardized guidelines based on expert consensus to assess patients for their inclusion into therapeutic trials for IIM have been published.⁹³ The International Myositis Assessment and Clinical Studies (IMACS) group and the Pediatric Rheumatology International Trials Organization (PRINTO) have been at the forefront of these efforts, which have led to remarkably similar outcome measures⁹⁴:

- Core set measures for assessment of disease activity in myositis trials (Table 148.4)⁹⁵
- Consensus on the minimum percent change in core set measures required to classify a patient as improved in a clinical trial⁹⁶
- Development of an international consensus on preliminary definitions of improvement in adult and juvenile myositis clinical trials^{94,97}
- A consensus document on the conduct of therapeutic trials for adult and juvenile myositis⁹³
- Inclusion of assessment recommendations for nonmuscular involvement, including constitutional features and cutaneous, articular, gastrointestinal, cardiac, and pulmonary manifestations⁹⁸

As a result of the IMACS and PRINTO workshops, considerable progress has been made in standardizing methods of assessing disease activity and damage in adult and pediatric myositis.^{94,99-101} Many other tools using newer diagnostic techniques such as changes in protein and gene expression

■ TABLE 148.4

Proposed preliminary core set measures for assessment of disease activity in adult and juvenile myositis clinical trials

Domain	Core set measures
Global activity	Physician global disease activity assessment by Likert or VAS; parent/patient global disease activity assessment by Likert or VAS
Muscle strength	MMT on a 0- to 10- point or expanded 0- to 5-point scale to include the proximal, distal, and axial muscles (adults and children >4 yr of age); validated method for age <4 yr (to be developed)
Physical function	Validated patient/parent questionnaire on activities of daily living (HAQ/CHAQ); validated observational tool of function, strength, and endurance (CMAS)
Laboratory assessment	At least two serum muscle enzyme activities from the following: CK, aldolase, LDH, ALT, and AST
Extramuscular disease	A validated approach that is comprehensive and assesses cutaneous, gastrointestinal, articular, cardiac, and pulmonary activity; the Myositis Disease Activity Assessment Tool is being validated

ALT, alanine aminotransferase; AST, aspartate aminotransferase; CK, creatine kinase; CMAS, Childhood Myositis Assessment Scale; CHAQ, Childhood Health Assessment Questionnaire; HAQ, Health Assessment Questionnaire; LDH, lactate dehydrogenase; MMT, manual muscle testing; VAS, visual analogue scale.

patterns in affected tissue will complement these outcome measures by providing molecular information that is pertinent to disease mechanisms in myositis.¹⁰²

Serum muscle enzymes

Enzymes that leak from injured skeletal muscle into serum are valuable aids in detecting ongoing muscle injury.¹⁰³

Serum CK is the most reliable enzyme test for use in routine patient care and predicts clinical events. During a flare of disease, serum CK levels will usually increase weeks before overt muscle weakness develops. Conversely, with treatment-induced remission, this enzyme decreases to normal levels before objective improvement in strength. There are exceptions, with some patients with active biopsy-proven myositis (DM > PM and children > adults) having normal CK levels and others having circulating inhibitors of CK activity. Moreover, there is considerable racial variation in CK concentrations such that reference values from white populations do not apply to black persons, in whom the upper limit of normal CK is higher. Serum myoglobin, which is cleared by the kidney, can be a useful marker of muscle damage and is elevated at least as frequently as serum CK.¹⁰⁴ Myoglobinemia is detected by nonenzymatic assays, but the test is cumbersome and not uniformly available. Urinary levels of muscle damage markers such as creatine, choline-containing metabolites, betaine, and citrate have been reported to correlate strongly with global disease damage in juvenile myositis.¹⁰⁵

Electromyography

Typical EMG findings include irritability of myofibrils at rest and on needle insertion (with fibrillation potentials, complex repetitive discharges, and positive sharp waves), as well as short-duration, low-amplitude, complex (polyphasic) potentials on contraction. More than 90% of patients with active myositis will have abnormal EMG findings, thus underscoring the fact that normal EMG findings tends to rule out myopathy or active disease in patients with myositis. EMG examination is helpful in selecting a muscle for biopsy but should be performed on only one side before biopsy of a contralateral muscle to avoid confusion resulting from inflammation artifact caused by injury from the needle itself.

Later in the course of disease, EMG examination may be helpful in detecting low-grade myositis in the setting of chronic damage from fibrosis or fatty infiltration. Glucocorticoid-induced myopathy causes some EMG changes, but the presence of fibrillation potentials suggests active inflammation.

Muscle biopsy

Although open biopsy represents the current “gold” standard for confirmation of the diagnosis of inflammatory myopathy, percutaneous needle muscle biopsy is a convenient and relatively inexpensive method with a high diagnostic yield in PM-DM^{106,107} and allows sampling of several muscles.

Degeneration and regeneration of myofibrils occur in 90% of cases. Chronic inflammatory cells in the perivascular and interstitial areas surrounding myofibrils are present in 80% of cases, but lymphocytic invasion of nonnecrotic MHC class I-expressing fibers is seen in PM (Fig. 148.11),

as well as in IBM. Besides lymphocytes, other cells may also be present, including histiocytes, plasma cells, eosinophils, and polymorphonuclear leukocytes. In chronic myositis, macrophages are seen phagocytosing necrotic fibers and muscle is replaced by fibrous connective tissue or fat. IMNM is also characterized by macrophagic myofiber necrosis, along with variable levels of sarcolemmal MHC class I expression and a relative paucity of lymphocytic infiltration.^{74,76}

There are important immunopathologic differences, however, between DM, PM, and IBM. In DM, B cells and the late component of complement (C5b-C9, membrane attack complex) predominate in the perivascular and perimysial area along with CD4+ T cells, macrophages, and dendritic cells. Perifascicular myofibril atrophy (Fig. 148.12), endothelial cell hyperplasia of blood vessels, deposition of immune complexes in the vasculature, and occasionally, frank vasculitis are noted. In contrast, PM and IBM feature cytotoxic T-cell invasion of myofibrils (Fig. 148.13) with relative sparing of the vasculature. CD4+ T cells, macrophages, and dendritic cells may also be found, primarily in perimysial areas, but unlike DM, B cells are rarely observed.

Magnetic resonance imaging

Application of magnetic resonance imaging (MRI) techniques adds an important diagnostic dimension to the assessment of myositis.¹⁰⁸ Large areas of muscle such as both thighs can be visualized, thereby facilitating selection of the most abnormal site for biopsy and increasing the diagnostic yield.¹⁰⁹ T1-weighted images provide excellent anatomic detail with clear delineation of various muscle groups. Normal tissue is homogeneously dark with a low signal, whereas fat (subcutaneous area and marrow) appears bright with correspondingly high signal intensity. Muscle is darker on T2-weighted images, whereas inflammation is bright on both T1 and T2 images. Adding fat suppression to the T2 technique in the form of short tau inversion recovery (STIR) sequences improves the detection of muscle inflammation by enhancing the bright signal of inflammation and decreasing the fat signal (dark) (Fig. 148.14).

Fig. 148.12 Transverse fresh frozen section of muscle from a patient with chronic dermatomyositis. Note the atrophic, small fibers in the periphery of the fascicles (perifascicular atrophy) and the increase in fibrous tissue separating bundles of myofibers (trichrome stain, low power).

Fig. 148.11 Longitudinal section of fresh frozen muscle from a patient with polymyositis. Several areas of interstitial involvement along with myofiber destruction are seen. The arrowhead indicates an area of degeneration and necrosis of myofibers in association with interstitial lymphocytic and histiocytic cellular infiltration (hematoxylin-eosin, medium power).

Fig. 148.13 Note the lymphocytic invasion of this intact, nonnecrotic myofiber in the muscle of a patient with polymyositis (hematoxylin-eosin, high power).

Based on these concepts, indications for MRI may include the following:

- Documentation of myositis or disease flare in a patient with normal CK, EMG, or biopsy findings
- Confirmation of ADM, in which case MRI should demonstrate no evidence of inflammation
- Distinguishing chronic active from chronic inactive myositis
- Directing the site of biopsy¹⁰⁹
- Clarifying the diagnosis in atypical cases of inflammatory myopathy and identifying noninflammatory mimics of myositis^{110,111}

Fig. 148.14 Fat-suppressed magnetic resonance image. Note the inflammation (white) in the muscles of the thigh in this longitudinal fat-suppressed image of a child with active dermatomyositis.

An area of recent interest is magnetic resonance spectroscopy, which can demonstrate the bioenergetics of normal and abnormal muscle.¹⁰⁸ Diffusion-weighted MRI can further quantify muscle inflammation and can potentially provide longitudinal monitoring of patients with myositis.¹¹²

Skin

The characteristic cutaneous histopathologic findings of DM include vacuolar alteration of the epidermal basal layer, necrotic keratinocytes indicative of apoptosis, vascular dilation, and a perivascular lymphocytic infiltrate.³¹ This “interface” pattern is similar to that seen with SLE and closely resembles the abnormal findings of a chronic graft-versus-host reaction.³¹ The histopathology of Gottron papules is similar to that observed in other skin lesions of DM. In the absence of other cutaneous features of DM, biopsy of Gottron lesions can be diagnostically useful.¹¹³ Vasculitis or vasculopathy is found in small cutaneous vessels. In turn, microvascular injury appears to be mediated by the terminal components of complement (C5b-C9) in the form of the membrane attack complex. Skin biopsy should therefore be performed in patients in whom the skin findings predominate and are not classic.

Nail-fold capillary microscopy is informative in many connective tissue diseases and is particularly beneficial in JDM, where it predicts severity, as well as the clinical course.^{114,115} A prospective study of nail-fold capillary microscopy in 53 consecutive adults with myositis noted 43% with relevant changes that correlated with disease activity and severity, particularly in DM.¹¹⁶

Serum autoantibodies

Serum autoantibodies are commonly found in PM-DM and are useful in defining clinically homogeneous subsets of patients. Antinuclear or anticytoplasmic antibodies are detected in more than 90% of patients with myositis.¹¹⁷ Although some antibodies are termed myositis-specific autoantibodies (MSAs), the specificity of MSAs is coming under closer scrutiny.¹¹⁸⁻¹²⁰ Autoantibodies typically associated with other connective tissue diseases may also be found in patients with myositis and are termed myositis-associated autoantibodies. Of note, a negative antinuclear antibody test does not exclude the presence of MSAs because antigen targets of the latter antibodies are cytoplasmic in location with subtle immunofluorescence staining patterns. Both MSAs and myositis-associated autoantibodies, along with their clinical associations, are outlined in Table 148.5.

Although a few patients have more than one serum autoantibody, multiple MSAs are rarely detected in the same patient.^{123,124} Anti-Jo-1, directed against histidyl-tRNA synthetase, is one of a group of anti-aminoacyl-tRNA

TABLE 148.5 Myositis-specific and myositis-associated autoantibodies in adult polymyositis and dermatomyositis and juvenile dermatomyositis

Autoantibody	Autoantigen	Clinical Features
Jo-1	Histidyl-tRNA synthetase	Fever, Raynaud phenomenon, mechanic’s hands, myositis, polyarthritis, ILD
SRP	Signal recognition particle (cytoplasmic protein translocation)	Severe necrotizing myopathy; predominantly PM
Mi-2	Helicase	DM (adult > children); “shawl” sign and other DM rashes
PM-Scl	Nucleolar macromolecular complex	Overlap features of myositis and SSc (or either disease alone); mechanic’s hands
U1RNP	Small nuclear ribonucleoprotein	Overlap syndromes (MCTD)
SUMO-1 (small ubiquitin-like modifier 1)	Small ubiquitin-like modifier enzyme (posttranslational modification)	Adult DM, ILD
p155/140	Transcriptional intermediary factor 1-γ (TIF1-γ)	Cancer-associated myositis in adults; >20% frequency in JDM cohorts; severe cutaneous disease in adult DM and JDM
Anti-p140 (also anti-MJ)	NXP-2 (SUMO target; possible role in SUMO-mediated transcriptional repression)	20-25% frequency in JDM cohorts; calcinosis; severe disease (atrophy/contractures)
cADM-140 (MDA-5)	RNA helicase	ADM, ILD; palmar papules and cutaneous ulcerations
PMS1	PMS1 (DNA mismatch repair enzyme)	Myositis (specifics not known)
Ku ¹²¹	70- and 80-kDa nuclear/nucleolar protein complex (DNA break repair and recombination)	UCTD and overlap syndromes (Raynaud phenomenon, ILD, myositis, arthritis)
200/100 kDa ^{76,122}	HMG CoA reductase	Necrotizing myopathy

ADM, omyopathic dermatomyositis; DM, dermatomyositis; HMG CoA, hydroxymethylglutaryl-coenzyme A; ILD, interstitial lung disease; JDM, juvenile DM; MCTD, mixed connective tissue disease; PM, polymyositis; UCTD, undifferentiated connective tissue disease.

TABLE 148.6
Anti-aminoacyl-tRNA synthetase antibodies and their associated antigens in polymyositis-dermatomyositis

Autoantibody	Autoantigen (tRNA synthetase)	Prevalence in idiopathic inflammatory myopathy (%)
Jo-1	Histidyl	20-30
PL-7	Threonyl	<5
PL-12	Alanyl	<5
OJ	Isoleucyl	<5
EJ	Glycyl	<5
KS	Asparaginyl	<1
Tyr	Tyrosyl	<1
Zo	Phenylalanyl	<1

synthetases (Table 148.6) and is the most common MSA—but still occurs in only 20% to 25% of individuals with myositis.

The clinical associations of the various antisynthetase antibodies are similar, but not all patients with an antisynthetase antibody will manifest every feature of the syndrome because myositis will never develop in some.^{86,125} For example, anti-PL-12 antibody-positive patients are more likely to have ILD without myositis, and the more recently described anti-synthetases such as anti-KS and anti-OJ are associated with less frequent myositis.^{126,127} Thus, the non-Jo-1 synthetases are more commonly associated with an incomplete antisynthetase syndrome or features of undifferentiated connective tissue disease. Anti-WS binds the L-shaped tertiary structure of tRNA and is therefore different from the other antisynthetases, but patients with this antibody also have recurrent fever, polyarthritis, and Raynaud phenomenon without myositis,¹²⁸ similar to patients with anti-tRNA synthetases.

Antibodies to signal recognition particle (anti-SRP) represent a separate subgroup of MSAs targeting a ribonucleoprotein involved in translocation. Initially thought to identify patients with pure PM and severe, refractory disease, this antibody has been reported in DM,¹¹⁸ as well as in patients with less severe muscle weakness and extramuscular manifestations such as ILD and arthritis.¹¹⁹ Nevertheless, anti-SRP is often associated with marked elevation of serum CK, severe muscle weakness, atrophy, and overall features reminiscent of limb-girdle muscular dystrophy. Novel autoantibodies against the 7SL RNA component of SRP have also been found, primarily in Japanese patients, two of whom had DM.¹²⁹

Among individuals with immune-mediated necrotizing myopathy who lack anti-SRP autoantibodies are those who possess antibodies targeting a 200/100-kDa complex identified as HMGCR.^{76,122} Clinical characteristics distinguishing statin users from statin nonusers with anti-HMGCR antibodies include older age, increased prevalence of white individuals, and a more favorable response to immunosuppressive therapy.^{122,130} The development of extramuscular complications is extremely rare in both subgroups of anti-HMGCR-positive IMNM.

Mi-2 is a multiunit protein complex that participates in regulation of transcription at the chromosome level. Anti-Mi-2 is an antinuclear antibody that can now be assessed by recombinant enzyme-linked immunosorbent assay (ELISA).¹¹⁸ Though thought to be exclusively associated with the rash of DM and a good response to immunosuppression, anti-Mi-2 has also been observed in patients with PM.¹³¹ Anti-Mi-2 is likewise seen in JDM and in malignancy, in which case the rash can be severe.

An antibody to the DNA mismatch repair enzyme PMS1 was found in 7.5% of a series of 153 sera from patients with myositis and has been proposed as a new MSA,¹³² but no unique or distinguishing clinical features have been identified.

Anti-PM-Scl is an antinucleolar antibody that identifies a subset of patients with myositis who often have features of SSc. This autoantibody may develop in patients with PM-DM or SSC or an overlap of both disorders. By using the PM-Scl-75 subunit in addition to the PM-Scl-100 epitope in ELISAs, an increased number of patients test positive for anti-PM-Scl autoantibodies.^{133,134}

Though not a true MSA, anti-U1-RNP antibodies generating a high-titer speckled pattern on routine antinuclear antibody testing can be associated with myositis, often in patients with so-called mixed connective tissue disease. Individuals with this antibody specificity may have various clinical manifestations of Raynaud disease, SLE, PM, DM, or SSc.

Antibodies to Ro/SSA are seen in at least 10% of patients with PM-DM and are particularly prevalent in individuals who also have antibodies to anti-aminoacyl-tRNA synthetases. The coexistence of anti-Ro/SSA and anti-Jo-1 antibodies may be associated with more severe ILD and a worse prognosis than the presence of anti-Jo-1 alone.^{52,53}

In recent years, new autoantibody specificities have been discovered in adult and juvenile IIM, but follow-up studies on larger cohorts of patients are necessary to validate these preliminary reports. Autoantibodies against a DM-specific autoantigen target—small ubiquitin-like modifier 1 (SUMO-1)-activating enzyme—were found in 8.4% of patients in a U.K. cohort, all of whom had DM.¹³⁵ A recently detected autoantibody against phenylalanyl-tRNA synthetase, anti-Zo, represents the eighth antisynthetase specificity linked with antisynthetase syndrome.¹³⁶

Found in adults with DM, autoantibodies directed against a 155-kDa protein or the 155/140-kDa doublet^{137,138} corresponding to TIF1-γ and related isoforms have proved to be highly specific, moderately sensitive, and highly predictive for malignancy-associated myositis.^{89,139} Antibodies against this same p155/140 target have also been detected in 23% of a JDM cohort and typically correlate with worse skin disease and ulceration than occurs in anti-p155/140-negative JDM cases.¹⁴⁰ Autoantibodies to a distinct 140-kDa protein in JDM were found to be associated with calcinosis in one study,³³ and autoantibodies to the same target autoantigen (termed 142-kDa anti-MJ) were associated with severe JDM in an Argentine cohort of patients.¹⁴¹ Finally, Sato and colleagues described a novel autoantibody termed anti-CADM-140 in adult Japanese patients with ADM and ILD.¹⁴² This antigenic target is distinct from the aforementioned anti-140-kDa, and the antigen has been identified as an RNA helicase encoded by *MDA5*.¹⁴²

OVERVIEW OF THE NATURAL HISTORY AND DISEASE PROGNOSIS

In some patients with DM (but rarely PM), a monophasic illness of brief duration may be followed by remission that does not require continued treatment. The majority of patients, however, have several exacerbations and remissions or persistent disease activity that necessitates chronic use of glucocorticoids or immunosuppressive drugs. The frequency of clinical and biochemical relapse was 34% to 60% in four series encompassing a total of 277 patients.¹⁴³⁻¹⁴⁷ The rate of relapse was greater in PM patients,¹⁴³ but no specific features predisposing to relapse were identified. Fluctuations in muscle strength are less dramatic in IBM, and a surprising proportion (a third) of untreated patients were stable or improved after 6 months of observation.¹⁴⁸

Each episode of myositis may be followed by loss of muscle mass and strength, often varying according to the clinical classification and serum autoantibody. The best functional outcome occurs in DM, whereas the worst occurs in IBM and PM with anti-SRP antibody. Patients with ADM lack muscle involvement, but malignancy and aggressive ILD can develop.^{24,86,149}

In JDM, predictors of chronic active myositis include failure to achieve normal muscle strength after 4 months of glucocorticoid treatment, continued elevation of muscle enzymes beyond 3 months, increased plasma von Willebrand factor antigen after 10 months of treatment,¹⁵⁰ and anasarca with hypoalbuminemia.¹⁵¹ A nonunicyclic course in JDM was associated with persistent nail-fold changes on capillaroscopy.¹¹⁴

PROGNOSTIC CONSIDERATIONS

Survival

Studies published before the availability of glucocorticoids reported that up to 50% of untreated patients with PM-DM die of complications; the improved survival and functional outcome over the last 40 years have largely been attributed to glucocorticoids. During the 1960s, large series described mortality rates approximating 40% after 5 years, whereas reports in the 1970s revealed only a 19% mortality rate. A recent summary of mortality in IIM noted 5-year survival rates ranging from 75% to 95%, with the variation being attributed to patient selection factors.¹⁵² Shorter survival is associated with certain cohorts, including myositis-associated malignancy,^{153,154} whereas populations enriched with overlap myositis, juvenile myositis, and those with a lower mean age at onset have better survival.^{155,156} The reasons for improved survival probably include earlier diagnosis, detection of milder cases, better general medical care, and more judicious use of immunosuppressive drugs.

Beyond malignancy and older age at onset,¹⁵⁷⁻¹⁵⁹ factors associated with poor survival include delayed initiation of glucocorticoid treatment,

pharyngeal dysphagia with aspiration pneumonia, ILD, myocardial involvement, and treatment complications. Although poor survival in JDM relates to gastrointestinal vasculitis and sepsis, children do well, with mortality rates of just 2% to 3%.¹⁶⁰

Among the serum autoantibodies, anti-SRP is a marker for a poor prognosis,^{2,119} followed by the antisynthetase group, in which mortality is driven by the severity of ILD. The best survival occurs in patients with anti-PM-Scl and anti-Mi-2 autoantibodies.

Disability

The determinants of functional status in myositis are different from those of survival. For example, IBM has the worst functional outlook but good survival stemming from the lack of visceral involvement.

Overall, a number of disease-related sequelae may contribute to the functional impairment in IIM, including calcinosis (especially in JDM), arthropathy, pulmonary insufficiency as a result of interstitial fibrosis, pulmonary hypertension or respiratory muscle involvement, and myocardial involvement with congestive heart failure or ventricular arrhythmias.

The contribution of glucocorticoid and immunosuppressive drug toxicity to long-term disability has not been addressed adequately, but the most commonly encountered side effects include osteoporotic bone fractures, osteonecrosis, cataracts, and serious bacterial or fungal infections. Factors predisposing to infections include pharyngeal muscle involvement (aspiration pneumonia), weakness of the respiratory muscles, and cutaneous calcinosis. Coupled with early cytopenias predisposing to septicemia, late hematologic malignancies represent a very real concern in patients with myositis and require traditional immunosuppressive drugs or newer biologic agents, or both.

Inflammatory muscle disease:
etiology and pathogenesis

■ INGRID E. LUNDBERG

- The major clinical features of myositis are muscle weakness and muscle fatigue.
- The major histopathologic findings of myositis consist of focal inflammation with T cells, macrophages, and dendritic cells, often together with injury, death, and repair of muscle cells (myocytes), and expression of major histocompatibility complex class I antigen on muscle fibers.
- Differences in the immunopathologic features with perivascular CD4+ T cells, B-cell infiltration, deposition of late complement components, and capillary loss, mainly in dermatomyositis, and endomysial infiltrates and activated CD8+ T cells and macrophage invasion of myocytes, mainly in polymyositis and inclusion body myositis, may reflect different etiologies and molecular pathways in different subsets of myositis.
- Myositis-specific autoantibodies, which target cytoplasmic molecules involved in protein synthesis, are associated with distinct clinical myositis subsets.
- The mechanisms that cause impaired muscle performance are likely to be a combination of cell-mediated muscle fiber necrosis, indirect effects of inflammatory cells by secretion of molecules that affect muscle fiber contractility, and an acquired metabolic myopathy secondary to loss of capillaries and local inflammation. Different molecular mechanisms may predominate in various phases of disease.

INTRODUCTION

The idiopathic inflammatory myopathies (IIMs) encompass a group of heterogeneous muscle disorders that share the clinical features of slowly progressive weakness of skeletal muscle, decreased muscle endurance, and muscle fatigue. Another common feature is the presence of inflammatory infiltrates, mainly composed of T cells, macrophages, dendritic cells, B cells, and plasma cells in muscle tissue. Autoantibodies are also frequently found in patients with inflammatory myopathies. The presence of infiltrating lymphocytes in the target organ and the muscles and the presence of autoantibodies suggest that the inflammatory myopathies are autoimmune diseases, but a target autoantigen has not been determined. On the basis of different clinical and histopathologic features, the IIMs can be subclassified into three major groups: polymyositis, dermatomyositis, and inclusion body myositis.¹ Another subclassification is based on the presence of autoantibodies, which are associated with distinctive clinical phenotypes such as antisynthetase syndrome.² The existence of these different clinical phenotypes, both those associated with different autoantibodies and those related to the categories of polymyositis, dermatomyositis, and inclusion body myositis, suggests that different pathogenic mechanisms are involved in the development of inflammatory myopathies. On the other hand, the predominating clinical symptoms of symmetric muscle weakness, mainly affecting proximal muscles, and decreased muscle endurance are shared by all the subsets of myositis, which indicates that some pathogenic mechanisms are shared.

Although muscle symptoms predominate in myositis patients, other clinical manifestations are common in polymyositis and dermatomyositis but not in inclusion body myositis. Besides skin rash, which by definition is present in dermatomyositis patients, interstitial lung disease is a frequently observed extramuscular manifestation, as are arthritis, Raynaud phenomenon, and gastrointestinal involvement (Table 149.1).^{1,3} Moreover, myositis is often observed in patients with other connective tissue diseases,

particularly in those with systemic sclerosis, mixed connective tissue disease, and Sjögren syndrome, and occasionally in patients with rheumatoid arthritis or systemic lupus erythematosus. These observations suggest that the IIMs are systemic inflammatory connective tissue disorders and that there could be etiologic factors or pathogenic mechanisms that are shared with other connective tissue diseases.

MUSCLE BIOLOGY AND PHYSIOLOGY

Skeletal muscle constitutes 40% of body weight and is instrumental for movements, joint protection, and maintenance in an upright position. Skeletal muscle is composed of striated muscle fibers, which are dependent on nerve and blood supply. The striated muscle fibers are multinucleated cells, and their length varies from a few millimeters to nearly 30 cm depending on body site.⁴ Each fiber is surrounded by a fine layer of connective tissue, the endomysium (Fig. 149.1). Several fibers, up to 150, form a fasciculus that is surrounded by another layer of connective tissue, the perimysium (see Fig. 149.1). Several fascicles form the muscle, which is surrounded by a fascia, epimysium.

Each muscle fiber is built up from ultrastructural functional units, myofibrils, that contain smaller units, myofilaments (see Fig. 149.1). In the myofilaments the contractile proteins myosin and actin make up 85% of all protein content.⁵ Other proteins that have structural functions or affect protein filament interactions are tropomyosin, troponin, desmin, and titin. The contractile unit in muscles is the sarcomere. The contraction is a Ca^{2+} -dependent process. Speed of contraction of a muscle depends on its myosin adenosine triphosphatase (mATPase) activity and is also correlated with specific isoforms of the contractile proteins. The speed-determining enzyme mATPase is associated with the myosin molecule. There are different isoforms of myosin with different contractile properties, depending on their heavy-chain isoform and mATPase activity. In adult muscle most individual muscle fibers are composed of only one myosin heavy-chain isoform. On the basis of mATPase activity or myosin heavy-chain isoform expression, three distinct fiber types have been described: slow type I, fast type IIA, and fast type IIB.⁶ Type IIB fibers are sometimes also called *type II X* or *type IID* in humans. A fourth fiber type, defined by mATPase reactivity, is an intermediate, undifferentiated, type IIC fiber. Type IIC fibers are regarded as transition fibers that can develop into either type I or type II fibers. Type I fibers contain the slow myosin heavy-chain isoform and type II fibers contain the fast myosin heavy-chain isoform. Type IIC fibers contain at least two different myosin isoforms (fast and slow) and developmental fetal myosin. Fiber types can also be differentiated using biochemical staining for mATPase at different pH values depending on the varying pH sensitivity of different mATPase reactivity. This information is used in clinical practice for histopathologic evaluation of muscle biopsy specimens from patients with neuromuscular problems (Fig. 149.2).

The different fiber types exhibit various physiologic properties. Thus type I fibers, slow twitch, are characterized by a relatively low mATPase reactivity and large and numerous mitochondria, which makes these fibers fatigue resistant and suitable for prolonged aerobic exercise and endurance work. Type II fibers, on the other hand, have a high mATPase activity, rely mainly on glycolytic systems for energy supply, and are important for quick, powerful actions. The specificity of fiber type in a muscle is established during development in the embryonic muscle and seems to be genetically determined.⁷

Each muscle is composed of a mixture of type I and II fibers, creating a checkerboard pattern (see Fig. 149.2). The ratio between the fiber types determines the physiologic properties of the muscle and differs between muscle groups. There are large interindividual variations in fiber type

TABLE 149.1
Affected organs and their evaluation in inflammatory muscle disease

Organ/system	Modalities of evaluation	Pathologic processes	Findings
Muscle	Biopsy	Myofiber degeneration-regeneration	Myofiber size variation; vacuolated, necrotic fibers
		Inflammation	Large central nuclei, basophilic sarcoplasm
		Fibrosis	Mononuclear cell infiltration
		Myofiber destruction	Increased interstitium and fatty replacement of muscle
Heart	EMG		Low-amplitude, short, polyphasic potential; spontaneous fibrillations; irritability
	MRI		
	T1 image	Fibrosis	Atrophy of muscle, scarring
	STIR image	Inflammation	Bright signal in inflamed muscle
Lungs	ECG, echo	Myocarditis, fibrosis	Arrhythmias, left ventricular hypertrophy
	Biopsy	Myocarditis, fibrosis	Myofiber size variation, mononuclear cell infiltrates, fibrosis
Gastrointestinal system	CXR, HRCT	Inflammation, fibrosis	Interstitial markings
	PFTs	Inflammation, fibrosis, restrictive lung disease	Decreased TLV and DLco
	Radionuclide scan	Inflammation, fibrosis	Ventilation-perfusion mismatches
	BAL	Inflammation, fibrosis	Abnormal leukocyte numbers and differentials
	Biopsy	Inflammation, fibrosis	Mononuclear cell infiltration, destruction of alveolar space and fibrosis
	Biopsy	Inflammation	Vacuolization of the basal layer; mononuclear cell infiltration
Skin	Biopsy	Inflammation	Vacuolization of the basal layer; mononuclear cell infiltration
Gastrointestinal system	Radiographic studies	Inflammation, fibrosis	Reflux and uncoordinated peristalsis

BAL, bronchoalveolar lavage; CXR, chest radiography; echo, echocardiography; DLco, diffusion capacity for carbon monoxide; ECG, electrocardiography; EMG, electromyography; HRCT, high-resolution computed tomography; MRI, magnetic resonance imaging; PFTs, pulmonary function tests; STIR, short tau inversion recovery; TLV, total lung volume.

Fig. 149.1 Individual myofibers (muscle cells or myocytes) are each surrounded by an endomysial membrane. Groups of myocytes are arranged into a bundle or fascicle and surrounded by the perimysium. Muscle fascicles are arranged together as functional units surrounded by a membrane known as the epimysial membrane. The vascular bundle consists of the artery and vein supplying the muscle cells.

composition.⁴ In athletes certain patterns of fiber type composition seem to be advantageous for different purposes. For example, marathon runners have a predominance of slow-twitch, type I fibers, whereas athlete sprinters and ice-hockey players have a predominance of fast-twitch, type II fibers.⁴ There is a tendency toward a gender difference with more type I fibers and smaller type II fibers in women than in men.⁸ With increasing age there are fewer type II fibers in both men and women.⁹

Muscle development and regeneration

During development, muscles are composed of single nucleated myoblasts that fuse into multinucleated myotubes; these myotubes then differentiate into mature muscle fibers.¹⁰ The phenotype of a developing muscle fiber differs from that of mature muscle fibers in the expression of molecules on the cell surface and in the cytoplasm or sarcoplasm. One characteristic phenotype of mature, differentiated muscle fibers is absence of major histocompatibility complex (MHC) class I molecules (human leukocyte antigen [HLA] A, B, C). MHC class I molecules are expressed on all nucleated cells in the body with few exceptions such as nerve cells and muscle cells. One important function of MHC class I molecules is to present endogenous antigens to the immune system via interactions with T-cell receptors. What role MHC class I molecules play during the development of muscle fibers and why mature muscle fibers lose MHC class I expression during differentiation are not known.

Muscle has a regenerating capacity depending on satellite cells, a kind of reserve cells localized under the basal lamina of the muscle fiber.¹⁰ On appropriate stimulation these satellite cells can grow and fuse with the fiber or develop into new adult muscle cells, a process termed *regeneration*. Regenerating fibers are often found in muscle biopsy specimens from patients with inflammatory myopathies. Like myotubes, regenerating fibers express MHC class I molecules on the sarcolemma and in the sarcoplasm.

ETIOLOGY

The etiology of myositis is likely to involve both genetic and environmental factors, but their relative contributions are largely unknown.

Genetic factors

The best-known genetic risk factors are certain HLA alleles, but the HLA genes that are associated with inflammatory myopathies vary in different populations around the world. HLA DRB1*0301 and the linked DQA1*0501 are the strongest known risk factors for all major forms of sporadic and familial types of myositis in white adults and children in both the United States and Europe.^{11,12} These alleles are part of the 8.1 ancestral haplotype (AH) (HLA-B*08-DRB1*03-DQA1*05-DQB1*02, 8.1 AH), which has even stronger associations with the presence of certain autoantibodies, the anti-synthetase autoantibodies, particularly anti-histidyl-tRNA (transfer RNA) synthetase (anti-Jo-1) antibody (see Table 149.3).¹² Anti-Jo-1 positivity is also associated with HLA-DPB1*0101 genotype.¹² Similarly, the DRB1*07-DQA1*02-DQB1*02 haplotype is associated with dermatomyositis, but it is even more strongly associated with possession of the dermatomyositis-specific anti-Mi-2 antibody.¹² Other associations have been reported for

Fig. 149.2 Fiber types as defined by adenosine triphosphatase staining at different pH levels in musculus vastus lateralis from a healthy person (a through c) and from a patient with polymyositis (d through f). At pH 4.3 the type I fibers are dark and type IIA and IIB fibers are unstained (a, d). At pH 4.6 the type I fibers are dark, IIA fibers are unstained, and IIB fibers are gray (b, e). At pH 10.3 type I fibers are unstained and type IIA and IIB fibers are dark (c, f). The intermediate type IIC fibers are gray at all pH levels and are present only in the biopsy specimen from the polymyositis patient. (Courtesy Ingela Loell.)

other ethnic groups.¹² The association with certain HLA class II genotypes supports the role of a T cell–driven immune response because the only known function of MHC class II molecules is to present antigens to antigen-specific T-cell receptors.

There are also genetic associations between myositis and non-HLA genes, such as tumor necrosis factor (TNF) gene, -308TNFA genotype and a polymorphism in the protein tyrosine phosphatase (PTP) N22 gene, involved in T-cell regulation.¹² The -308TNFA gene is localized within the conserved ancestral haplotype on chromosome 6, mentioned earlier, and the TNF gene association is due to linkage disequilibrium with the extended ancestral haplotype.¹²

Although there is accumulating evidence that genetic factors are involved in the development of IIMs, it is clear that the genetics are complex as in other chronic inflammatory diseases. Furthermore, it is likely that environmental risk factors interact with genetic factors, but so far there is no information on such interactions in myositis.

Environmental factors

The environmental factors most frequently reported to be associated with muscle inflammation are drugs and infections. Other factors are ultraviolet (UV) light, vitamin D deficiency, and smoking.

Infections

Cases of muscle inflammation with histopathologic resemblance to polymyositis have been described in patients with specific infections. The most frequently reported cases have been in patients infected with the retroviruses human T-cell leukemia/lymphoma virus type 1 and human immunodeficiency virus and in those infected with the parasite *Trypanosoma cruzi*.¹³ However, there has been no success in detecting signs of a preceding or persisting infection in myositis cohorts, and thus solid evidence is still lacking for any role of continuing viral infections as a cause of the chronic muscle inflammation.

Ultraviolet light and vitamin D deficiency

An environmental factor that could be important in the cause and pathogenesis of myositis is UV radiation. The relative proportion of dermatomyositis cases, as well as the proportion of patients with anti-Mi-2 antibodies,

correlates with UV radiation intensity, with dermatomyositis clearly being more common close to the equator (Guatemala and Mexico) than close to the north pole (Iceland and Sweden).¹⁴ The association between UV light exposure and subtype of myositis suggests that UV light is an exogenous modifier that can influence the clinical phenotype in two closely related diseases, polymyositis and dermatomyositis.

Low serum levels of vitamin D have been reported in several autoimmune disorders including adult myositis, which suggests that vitamin D deficiency is a risk factor for the development of autoimmune diseases.¹⁵ Vitamin D has several roles in the regulation of the immune system, but the exact mechanisms in the development of autoimmunity is not known.

Drugs

Several drugs may induce myopathies with muscle weakness and increased serum levels of creatine phosphokinase resembling inflammatory myopathies (see Table 149.2). The most common cause of drug-induced myopathy in recent years is lipid-lowering agents, including statins, fibrates, and nicotinic acid.¹⁶ Predominating clinical features in statin-induced myopathy are muscle pain and cramps, but in rare cases severe rhabdomyolysis with a risk of renal failure may develop. Statin-induced myopathy is usually not characterized by inflammatory cell infiltrates in muscle tissue and in most cases is reversible after the drug is stopped. If muscle symptoms persist after the lipid-lowering drug is stopped, one should consider the possibility that the drug has triggered an underlying myopathy such as a metabolic myopathy. The mechanisms whereby these drugs cause myopathies have not been clarified, but statins are hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors, and this inhibition may interfere with energy production, which may give rise to symptoms in muscle fibers. Recently a necrotizing myopathy associated with autoantibodies directed against HMG-CoA reductase (anti-HMGCR [anti-200 kDa/100 kDa]), the target of statins, was reported.¹⁷ This myopathy is associated with the use of statins and HLA-DRB1*11:01 genotype.¹⁸ These observations may suggest a mechanistic link between statin exposure, increased HMGCR expression, and the possible presentation of HMGCR-derived peptide(s) by DRB1*11:01. These patients often respond to immunosuppressive agents. Tests for anti-HMGCR antibodies are not yet commercially available.

In general, drug-induced myopathies can be distinguished from inflammatory myopathies by the history of drug use, the absence of characteristic histopathologic changes in muscle biopsy specimens, and the occurrence of

TABLE 149.2

Drugs and toxins that may induce myopathy

Examples	Comments
Cimetidine	
Chloroquine	Vacuolar myopathy
Colchicine	Vacuolar myopathy
Emetine	
Ethanol	Acute rhabdomyolysis and chronic myopathy
Glucocorticoids	Type II fiber atrophy
Heroin	
Penicillamine	Typical polymyositis Mitochondrial myopathy
Statins and fibrates	Cases of necrotizing myopathy, polymyositis, rhabdomyolysis, and noninflammatory myopathies reported
Zidovudine (AZT)	
(Many others reported at the case level)	

clinical improvement when the drug is stopped. Also, glucocorticoids may induce a myopathy that, by itself, is not associated with any histopathologic changes reminiscent of inflammatory myopathy. The fact that glucocorticoid-induced myopathy may also be induced in patients with inflammatory myopathies during treatment with glucocorticoids raises an obvious diagnostic problem. The diagnosis of glucocorticoid-induced myopathy in patients with myositis thus can be established only when strength improves with lowered doses of prednisone.

An inflammatory myopathy with infiltration of inflammatory cells in muscle tissue resembling polymyositis or dermatomyositis has been reported in a few cases after treatment with interferon- α (IFN- α).¹⁹ There are also a few reports of signs of an inflammatory myopathy in patients with rheumatoid arthritis after treatment with TNF-blocking agents.²⁰ Whether these cases developed due to mere chance or whether the interference with the immune system caused by these agents triggered onset of a myositis needs to be further evaluated.

Smoking

An association between smoking and anti-Jo-1-positive myositis in patients with an HLA-DRB1*03 genotype was recently reported, which suggests a gene-environment interaction.²¹ Whether smoking is a risk factor for the development of myositis in general has not yet been investigated.

Malignancy

A strong association exists between malignancy and dermatomyositis, but the link is less clear with polymyositis.²² The increased risk involves different types of tumors.²³ Whether this association is due to a paramalignant phenomenon (i.e., development of myositis subsequent to the malignancy) or chronic inflammation contributing to the development of malignancies is not clear. Circumstantial evidence exists for a paramalignant phenomenon from reports of cases in which removal of the tumor has led to disappearance of the dermatomyositis. The clinical implication of the association, irrespective of the pathogenic mechanisms, is to search for tumors in patients with dermatomyositis. Recently a novel autoantibody, anti-transcriptional intermediary factor-1 γ (TIF-1 γ , or anti-p155/140), was reported to have a sensitivity of 78% and a specificity of 89% for diagnosing cancer-associated dermatomyositis.²⁴ An antibody test is not yet commercially available, but the autoantibody can be detected in serum by immunoprecipitation.

PATHOGENESIS

The presence of T lymphocytes in muscle tissue in a majority of patients with myositis and the frequent detection of autoantibodies indicate that immune mechanisms are involved in the pathogenesis of these disorders and that both T and B cells may have a pathogenic role (Box 149.1). The

BOX 149.1 IMMUNOLOGIC ABNORMALITIES IN PATIENTS WITH INFLAMMATORY MYOPATHIES

Cellular abnormalities

T-cell receptor restriction in inflamed muscle
Activated T and B lymphocytes expressing costimulatory molecules: CD86/CD80; CD28/CTLA4; CD40/CD40L in skeletal muscle
Increased peripheral mononuclear cell trafficking to muscle
Increased proportions of peripheral T and B lymphocytes bearing activation markers
High frequency of CD4+ CD28^{null} and CD8+CD28^{null} T cells in peripheral blood and muscle tissue
Type I interferon gene expression in muscle tissue and peripheral blood of dermatomyositis and polymyositis patients
High expression of proinflammatory cytokines and chemokines in muscle tissue (IL-1 α , IL-1 β , tumor necrosis factor, high-mobility group box 1, vascular endothelial growth factor, macrophage inflammatory protein 1 α)
Elevated serum levels of IL-1 α , IL-2, soluble IL-2 receptors, and soluble CD8 receptors
Decreased proliferative responses of peripheral mononuclear cells to T-cell mitogens
Increased proliferative responses of peripheral mononuclear cells to autologous muscle
Increased expression of cytokines and chemokines in infiltrating mononuclear cells and muscle cells
Increased expression of MHC class I (HLA-ABC), class II (HLA-DR), and intercellular adhesion molecule 1 on skeletal muscle fibers

Humoral abnormalities

Immunoglobulin and complement deposition in muscle vascular endothelium
Presence of myositis-specific autoantibodies (see Table 149.3)
Presence of myositis-associated autoantibodies (anti-U1RNP, anti-PM/Scl, anti-Ku)
Presence of other autoantibodies (anti-thyroid, anti-Sm, anti-Ro, anti-La, etc.)
Hypergammaglobulinemia, hypogammaglobulinemia, and agammaglobulinemia
Monoclonal gammopathy

HLA, human leukocyte antigen; IL, interleukin; MHC, major histocompatibility complex.

antigen specificities have not been clarified, and it is still not known whether muscle-specific immune reactions are involved and whether such reactions differ among various subsets of myositis.

Three major effector mechanisms have been proposed to be important for the development of chronic muscle inflammation and the major clinical symptoms, muscle weakness and muscle fatigue:

- Direct effects of infiltrating leukocytes, mainly T lymphocytes and macrophages, on muscle cells (e.g., by means of cytotoxicity)
- Indirect effects of molecules from the immune system (cytokines and others) on muscle metabolism and function
- Involvement of microvessels and a disturbed microcirculation, which could lead to acquired metabolic disturbances and thereby cause reduced muscle function

We could potentially learn about the operative pathogenic mechanisms in human diseases in several ways, through studies in animal models, through *in vitro* studies of cell or tissue cultures, or, most conclusively, from studies of the disease course and the target organ during administration of therapies targeting distinct molecules or mechanisms. Until recently, animal models have been of limited value in studies of myositis due to the lack of a model with a chronic muscle inflammation and associated histopathologic and clinical features resembling human polymyositis, dermatomyositis, or inclusion body myositis, but two promising animal models have now been developed, the MHC class I transgene and the C-protein myositis model, in which some aspects of myositis can be studied.^{25,26} Some information has also been gained from *in vitro* studies of cultured myoblasts and myotubes, which have demonstrated that the responsiveness and strength of cultured muscle cells are diminished after exposure to some cytokines, notably TNF.²⁷ The most informative studies have been performed in carefully characterized myositis patients with defined different clinical phenotypes and in different phases of their disease, as well as after different therapies. Such studies are based on characterization of the phenotypes of resident and infiltrating cells and distribution of molecules of potential pathogenic importance, as discussed next.

Fig. 149.3 Muscle tissue changes in myositis by light microscopy. (a, b) Cross-sectional views of inflammatory myopathy showing variation in cell size, necrosis, regeneration, and inflammation in polymyositis (a) and dermatomyositis (b) (hematoxylin-eosin). (c) Perifascicular atrophy in dermatomyositis (major histocompatibility complex class I antigen, immunohistochemical staining). (d) Red-rimmed vacuoles, marked cell-size variation, and relatively sparse inflammation in inclusion body myositis (trichrome stain). (c, Courtesy Dr. I. Nennesmo.)

Muscle histopathologic features

Characteristic histopathologic signs in patients with inflammatory myopathies are the presence of mononuclear inflammatory cell infiltrates in muscle tissue and degenerating, necrotic fibers, as well as regenerating muscle fibers (Fig. 149.3a and b).^{1,3,28} Atrophy of muscle fibers in a perifascicular fashion is found mainly in patients with dermatomyositis, often in a later phase of the disease (Fig. 149.3b and c). In inclusion body myositis, rimmed vacuoles are characteristic features that can be seen under a light microscope (Fig. 149.3d).¹ Nuclear or cytoplasmic inclusions are detected mainly by electron microscopy. None of these features in biopsy specimens is pathognomonic for myositis; all may also occur in other disorders, and they are not directly linked to muscle function. Importantly, these histopathologic features are often focal, and in some cases a muscle biopsy specimen can look normal despite clinically evident muscle weakness. Furthermore, the degree of histopathologic features is not correlated with the degree of muscle weakness. The focal nature of inflammation is also observed by magnetic resonance imaging, which can detect inflammation as a bright signal using the short tau inversion recovery (STIR) sequence (Fig. 149.4). The reasons for this heterogeneity of muscle inflammation are not known, but the heterogeneity suggests that not only does immune-mediated muscle fiber damage cause impaired muscle function but other mechanisms are also important, as discussed next.

Immunopathologic features

Careful characterization of human muscle tissue from patients with myositis using immunohistochemistry has revealed that there is a tendency for different lymphocyte subsets to accumulate in different regions of the muscle, which suggests that there are different targets of the immune reaction. The pattern of distribution of inflammatory cells also tends to vary for different clinical subsets of myositis.²⁹

Basically two different patterns of inflammatory cell infiltrates are found in muscle tissue in adult inflammatory myopathies. One is predominantly localized to the endomysium and is composed mainly of CD8+ and CD4+ T cells, macrophages, and dendritic cells.^{1,3,28,29} In some cases the infiltrates surround and seem to invade nonnecrotic muscle fibers (Fig. 149.5a).²⁸ This feature is seen predominantly in polymyositis and inclusion body myositis (see Fig. 149.5a).²⁸ The other pattern has a perivascular and perimysial localization and is composed mainly of CD4+ T cells, macrophages, dendritic cells, and B cells.^{1,3,28,29} This pattern is seen predominantly in dermatomyositis cases.^{28,29} These different immunohistopathologic features suggest that different pathogenic mechanisms could be involved in the different subsets of myositis, with a predominance of T cell-mediated muscle fiber damage in polymyositis and inclusion body myositis and a role for the microvessels in dermatomyositis (Fig. 149.5b). However, these changes are not strictly related to the presence or absence of skin rash. Recently further phenotyping of T cells has found CD28^{null} T cells of both CD4+ and CD8+

Fig. 149.4 Magnetic resonance images of the thigh. In cross section using the short tau inversion recovery technique, atrophy of the anterior muscles is evident. Inflammation shows up as bright areas in the posterior muscles. (Courtesy Dr. J. Frank and Dr. D. Fraser.)

phenotypes to dominate in both muscle tissue and peripheral blood in all three subsets of myositis.^{30,31} CD28^{null} T cells are proinflammatory, can be easily activated, and have cytotoxic capacity. Furthermore, they are apoptosis resistant and could contribute to the chronicity of disease, which makes them interesting as targets for therapy. CD28^{null} T cells have a restricted T-cell receptor (TCR) repertoire, which suggests that they are locally expanded.³¹ Another enigma in myositis is that in many patients the inflammatory cellular infiltrates are sparse and do not correlate with the degree of muscle symptoms, which suggests that other components of the immunopathology of inflamed muscle are also important for the disease. In contrast, the tissue distribution of signaling molecules produced in inflamed muscle tissues such as cytokines and chemokines does not seem to differ in various subsets of myositis, which indicates that some molecular mechanisms may be shared by different subsets of myositis.³²

Another feature of inflamed muscle tissue is expression of MHC class I and II molecules in muscle fibers, which normally do not express these antigens (Fig. 149.6).³³ MHC class I antigen expression is present in a majority of myositis patients both on regenerating fibers and on otherwise histopathologically normal-appearing muscle fibers. The MHC class I expression is localized to the muscle fiber membrane and often diffusely spread within the sarcoplasm. Furthermore, the MHC class I and class II expression on muscle fibers has been observed even in the absence of inflammatory cell infiltrates.³⁴ The MHC class II molecules are less consistently expressed, mainly on scattered muscle fibers. The mechanisms by which MHC class I and class II expression are induced on muscle fibers *in vivo* have not been clarified, but from *in vitro* studies it has been demonstrated that proinflammatory cytokines or chemokines may induce MHC class I and class II

Fig. 149.5 (a) Lymphocytes invading a myocyte in a patient with myositis (double immunofluorescent staining with anti-CD8 [green] and anti-DR [red] antisera). Distribution of CD4+ and CD8+ lymphocytes in different clinical forms of myositis: In dermatomyositis inflammatory infiltrates consist predominantly of perivascular B and CD4+ T cells, and in polymyositis and inclusion body myositis they are mostly endomysial CD8+ T cells. (b) The complement membrane attack complex in the vessels of a muscle from a patient with dermatomyositis. (a, Courtesy Dr. J.T. Kissel; b, courtesy Dr. Andrew Engel.)

Fig. 149.6 Major histocompatibility complex (MHC) class I antigen expression detected by immunohistochemistry in muscle tissue. (a) In normal muscle, positive staining (brown) is seen mainly in capillaries. (b) In a patient with polymyositis, positive staining (brown) is localized to muscle fiber membranes, is seen diffusely in the sarcoplasm of several fibers, and appears on inflammatory cells localized in the endomysium.

expression on cultured muscle cells.³⁵ These include cytokines that have been detected in inflamed muscle tissue such as type I IFNs, IFN- γ , interleukin-1 α (IL-1 α) and IL-1 β , and TNF- α . A possible role of the induction of MHC class I molecules on muscle fibers in the pathogenesis of myositis is discussed in the following section. The MHC class I expression on muscle fibers, although not specific for myositis, could be helpful in diagnostic evaluation to distinguish affected muscles from normal muscle.³⁶

Cytokines and chemokines

A number of cytokines and chemokines that may play a role in the pathogenesis of myositis have been detected in muscle tissue from patients with these disorders. The most frequently reported cytokines in IIMs are the proinflammatory cytokines IL-1 α , IL-1 β , TNF- α , and type I IFNs and the alarmin high-mobility group box 1 (HMGB1).^{32,37,38} Other cytokines that have been found with increased expression in muscle tissue on the protein or messenger RNA level are IL-4, IL-6, IL-15, IL-17, and IL-18.³² The proinflammatory type I IFNs (IFN- α and IFN- β), which are produced mainly by plasmacytoid dendritic cells, were found with pronounced gene expression in muscle tissue and peripheral blood and with a suggestive association with disease activity in polymyositis and dermatomyositis.³⁹ A majority of these cytokines are present in inflammatory cells; some cytokines, such as TNF- α , IL-6, and IL-15, are also observed in the cytoplasm of muscle fibers, and still other cytokines (e.g., IL-1 α) are found mainly in endothelial cells, even when inflammatory cells are not detectable in the vicinity.³² Another prominent molecule in muscle tissue is transforming growth factor- β (TGF- β).^{32,37} TGF- β has antiinflammatory effects and could stimulate the development of fibrosis. Despite the different patterns of infiltrating inflammatory cells in different subtypes of myositis, the cytokine pattern in muscle tissue is with few exceptions similar in the different subsets of myositis.

Chemokines are inflammatory mediators that have chemotactic functions in attracting leukocytes to tissues. They are produced by a number of different cells including endothelial cells, fibroblasts, and lymphocytes and are secreted and bound to receptors on target cells (e.g., monocytes, lymphocytes). The main stimuli for chemokine production are proinflammatory cytokines such as IFN- γ , IL-1, TNF- α , bacterial products, and viral infections. The α -chemokines CXCL9 and CXCL10 and the β -chemokines CCL2, CCL3, CCL4, CCL19, and CCL21 are expressed in muscle tissue from myositis patients.⁴⁰ Some differences in chemokine expression have been observed between patients with dermatomyositis and those with polymyositis and inclusion body myositis. Dermatomyositis is characterized by high levels of CXCL12 and CCL2 in affected blood vessels and the B-cell activator CXCL13 is particularly prominent in the larger perimysial infiltrates of dermatomyositis,⁴⁰ whereas CXCL10 and CCL2 are expressed on infiltrating cells in muscle tissue in polymyositis and inclusion body myositis.⁴⁰

Immune mechanisms and muscle function

In addition to the previously described characteristic cellular infiltrations of T cells, restricted TCR use by muscle-infiltrating cells in polymyositis and inclusion body myositis provides additional support for a role of T cell-mediated muscle-specific immune reactivity. This restriction suggests that subpopulations of T cells are selected and expanded in muscle tissue in response to as yet uncharacterized antigens. In dermatomyositis the TCR patterns are more polyclonal. Although oligoclonal TCR patterns have been observed in polymyositis and inclusion body myositis, no consistent TCR repertoire has been identified to date.

The most common way to initiate an immune response is through professional antigen-presenting cells (e.g., dendritic cells or macrophages), which capture antigens in the peripheral tissue and then migrate to lymphoid

organs, where they present the antigenic peptides to antigen-specific T cells, initiating the expansion and maturation of helper (CD4+) and effector (CD8+) T cells.⁴¹ Both myeloid and plasmacytoid dendritic cells have been demonstrated in muscle tissue from patients with all subsets of myositis.⁴² Whether muscle fibers with MHC class I or class II expression may act as antigen-presenting cells and thereby interact with T cells is still uncertain. The muscle fibers may express additional cell-surface molecules (intercellular adhesion molecule 1 [ICAM-1] and CD40), but the costimulatory molecules (CD80/CD86) that customarily induce immune stimulation have not been demonstrated convincingly on muscle cells.⁴¹

Mechanisms of cell damage

The relationship between infiltrating inflammatory cells and muscle dysfunction is still unclear. One possibility is T cell-mediated muscle fiber death, but as mentioned earlier there is no clear evidence of an interaction between TCRs and MHC class I or II molecules on muscle fibers. Furthermore, the observation that the surface membrane of muscle fibers in the inflamed tissue remains intact (as indicated by both light microscopic and electron microscopic data), despite the close proximity of the inflammatory cells, argues against a direct cytotoxic effect of CD8+ T cells on muscle cells. Apoptosis of the muscle fibers has also been proposed as a mechanism for muscle fiber degeneration, but despite the efforts of several research groups, no one has succeeded in detecting signs of apoptosis of the muscle cells in muscle biopsy specimens from patients with myositis.⁴³ Some studies suggest that the resistance to undergoing Fas/TNF receptor-mediated apoptosis is due to expression in the muscle fibers of proteins that inhibit apoptosis; namely, Fas-associated death domain-like IL-1-converting enzyme inhibitory protein (FLIP), inhibitor of apoptosis protein-like protein (hILP), and Bcl-2.⁴⁴ Cytotoxic mechanisms mediated by perforin and granzyme were also suggested as mechanisms for cell damage in myositis, and perforin-containing granules within CD8+ T lymphocytes have been found oriented toward adjacent muscle fibers.⁴⁵ The expected porelike structures in the sarcolemma from perforin exposure could not be detected, however, so it is still uncertain whether this mechanism has any role in mediating direct T cell-mediated damage in myositis patients.

Indirect effects of molecules from the immune system (cytokines and others) on muscle metabolism and function

Because patients can have muscle weakness and decreased muscle endurance without detectable inflammatory infiltrates and muscle fiber cell apoptosis or necrosis, mechanisms other than direct cell-mediated muscle fiber damage could be involved in the disease mechanisms that cause impaired muscle function. Another possibility is that soluble factors such as cytokines or chemokines affect muscle fibers either by direct toxic effects that induce fiber degeneration or through effects on muscle fiber metabolism or contractility. As an example, TNF- α and HMGB1 may have profound effects on muscle function, causing muscle fiber contractile dysfunction.^{27,46} TNF also has a catabolic effect on muscle cells by mediating protein loss and insulin resistance; it inhibits regeneration of muscle fibers and is an important mediator of muscle atrophy associated with cachexia.²⁷ IL-1 α is known from *in vitro* studies to inhibit production of insulin-like growth factor, which leads to metabolic disturbances in nutrition supply. IL-1 α may also inhibit muscle regeneration through suppression of myoblast proliferation and myoblast fusion.³⁵

IL-1 α seems to be of particular interest in myositis because this cytokine was consistently found in endothelial cells of microvessels in muscle tissue from myositis patients who had muscle weakness in both the early and the late, chronic phase of disease as well as persisting muscle weakness after treatment with glucocorticoids. Furthermore, IL-1, IFN- α , IFN- γ , TNF and HMGB1 all have the capacity to induce expression of the MHC class I molecules on muscle fibers, a typical feature in myositis.^{33,34,35,46}

The results of studies targeting specific molecular pathways will provide more information on the relative role of these molecules in the disease mechanisms of inflammatory myopathies. The experience in using targeted therapies that block specific molecules in the inflammatory cascade is limited to date in myositis. Treatment with TNF blockade has had varying effects on muscle function and muscle tissue inflammation, which makes the role of TNF in the pathogenesis of myositis uncertain.⁴³ IL-1 is clearly a potential target for directed therapies in myositis, but limited data are available to date on the use of agents blocking this molecule.

The MHC class I antigen expression on muscle fibers may also have a direct effect on muscle function. This notion is supported by the observation of MHC class I expression on the muscle fibers of myositis patients with clinical muscle weakness even in the absence of detectable inflammatory infiltrates.³⁴ Another line of support comes from studies of an animal model in

which conditional upregulation of MHC class I molecules on muscle fibers causes transgenic mice to develop muscle weakness, which precedes the histopathologic inflammation.²⁴ The mechanism by which the MHC class I upregulation induces muscle weakness could be endoplasmic stress affecting the synthesis of proteins that are important for energy substrates and contractility.³⁷

Involvement of the microvasculature in inflammatory myopathies

A third possibility for disease mechanisms that affect muscle function in myositis is involvement of the microvessels. Clinical signs indicating microvessel involvement such as the presence of nail splinters are found mainly in patients with dermatomyositis. Histopathologic observations of a decreased number of capillaries in muscle tissue were initially reported in patients with dermatomyositis.⁴⁸ This was seen even in early cases with muscle symptoms but without inflammatory cellular infiltrates. Localization of the late components of the complement system (C5 to C9, the membrane attack complex) (see Fig. 149.6b) to the areas with fewer capillaries suggests a vascular injury, which may even precede the infiltration of inflammatory cells and lead to muscle fiber damage.

Other abnormal phenotypic changes of blood vessels have been observed in muscle tissue not only from patients with dermatomyositis but also from those with polymyositis and inclusion body myositis. These changes include thickening of the endothelial cells both of capillaries and venules to resemble the endothelial cells of high-endothelium venules (HEVs), which have a central role in lymphocyte homing. This endothelial phenotype together with increased expression of the adhesion molecules ICAM-1 and vascular cellular adhesion molecule 1 suggest that the endothelial cells are activated. The corresponding ligands, LFA-1 and VLA-4, are also present on inflammatory cells in muscle tissue in myositis patients. HEV-resembling endothelial cells with increased expression of IL-1 α have been observed in areas exhibiting cellular infiltration and areas without inflammatory cells and in both patients with new-onset polymyositis and dermatomyositis and patients with chronic disease who experience persisting muscle weakness after immunosuppressive treatment.³² Interestingly, these changes correlated better with the persisting decrease of muscle function than did the inflammatory infiltrates. The activated microvessels with expression of adhesion molecules could promote migration of inflammatory cells into the muscle tissue and thereby play a central role in pathogenesis not only in dermatomyositis, as was suggested earlier, but also in polymyositis and inclusion body myositis. Adhesion molecules could also be attractive molecules for targeted therapies in these conditions.

Another possible consequence of microvessel involvement is a secondary metabolic disturbance and muscle tissue hypoxia. This is indicated by reduced levels of adenosine triphosphate and phosphocreatine observed by magnetic resonance spectroscopy, which reflect an abnormal energy metabolism in muscle tissue.⁴⁹ Hypoxia could also be generated in chronically inflamed tissue, as has been demonstrated in the synovial tissue of patients with rheumatoid arthritis. Low oxygen tension was also observed *in vivo* in muscle tissue in a small study of myositis patients.⁵⁰ Another finding supporting the hypoxia hypothesis is that two of the most frequently detected cytokines in muscle tissue, IL-1 and TGF- β , could be induced by hypoxia. In addition, patients with polymyositis and dermatomyositis had a high level of expression of the potent proangiogenic peptide vascular endothelial growth factor in both muscle tissue and sera compared with healthy controls.⁵¹ Local tissue hypoxia could contribute to mitochondrial dysfunction as indicated by the increased number of ragged red fibers and cytochrome c oxidase-negative fibers observed in inflammatory myopathies, which is most pronounced in dermatomyositis and inclusion body myositis. In chronic polymyositis and dermatomyositis with persisting impaired muscle function, a low proportion of oxidative, type I fibers was detected in thigh muscles, which could be a consequence of local tissue hypoxia.⁵⁰ Interestingly, this was reversed by physical exercise, with improved muscle performance.⁵² A combination of factors, including both immune-mediated muscle cell death and activation of different molecular pathways with an acquired metabolic myopathy, are likely to contribute to muscle weakness and fatigue in polymyositis and dermatomyositis. Sufficient data support this combination of pathogenic pathways to support their consideration when treatment regimens are designed, but the key molecular pathways are still unclear and further research is needed.

Humoral mechanisms

Humoral mechanisms in the pathogenesis of IIMs are suggested on the basis of two observations. The first is the presence of autoantibodies, and the second is deposition of complement and immunoglobulins in microvessels

LABORATORY DEMONSTRATION OF MYOSITIS-SPECIFIC AUTOANTIBODIES

Fig. 149.7 (a) Cytoplasmic staining of cultured human cells by immunofluorescence using serum from a patient with anti-glycyl-transfer RNA (tRNA) synthetase antibodies. (b) Immunoprecipitation of cell extract by sera from patients with some myositis-specific autoantibodies. Only the RNA of the protein-RNA immunoprecipitate is shown. 1, normal; 2, anti-signal recognition particle (SRP); 3, anti-threonyl-tRNA synthetase (PL-7); 4, anti-histidyl-tRNA synthetase (Jo-1); 5, anti-isoleucyl-tRNA synthetase (OJ); 6, anti-alanyl-tRNA synthetase (PL-12), accompanied by anti-Ro, anti-La, and anti-RNP; 7, anti-glycyl-tRNA synthetase (EJ). (a, Courtesy D. Gracey; b, courtesy Dr. S. Cochran.)

in muscle biopsy specimens, as described earlier. Autoantibodies are present in 55% to 80% of myositis patients.⁵³ The most common autoantibodies are antinuclear antibodies, which are seen in all subsets of myositis but are less common in inclusion body myositis (30%).⁵³ No autoantibodies directed against muscle-specific antigens have been identified in myositis patients so far. Some of the autoantibodies detected are present in other inflammatory connective tissue diseases, even without signs of myositis, and are often called *myositis-associated autoantibodies* (e.g., antiribonucleoprotein [anti-RNP] antibodies), whereas others are found mainly in patients with IIM and therefore called *myositis-specific autoantibodies* (MSAs).²

The MSAs are particularly interesting in a pathogenic context not only because they are found almost exclusively in patients with myositis but also because they are associated with distinct clinical features and distinct genotypes. Because certain antibodies are associated with distinct extramuscular clinical features, their detection can be helpful to confirm a diagnosis of myositis and also to classify myositis patients into distinct clinical subgroups as described later. Interestingly, the presence of MSAs is associated with different HLA class II genotypes as described earlier in the discussion on genetics. The MSAs are often present at the first visit to the physician. In most patients they remain present during the disease course, although some (e.g., anti-Jo-1 antibodies) may vary with disease activity.⁵⁴ A common feature of these autoantigens is that they are cytoplasmic and thus do not induce the production of “antinuclear” antibodies; instead, they show a diffuse cytoplasmic pattern of staining of target cells when exposed to sera from patients with some MSAs (Fig. 149.7). These autoantigens are usually part of the protein synthesis machinery (Fig. 149.8).

The most frequently found MSAs are those directed against the aminoacyl-tRNA synthetases, a group of cytoplasmic enzymes that attach tRNAs to the corresponding amino acids (catalyze formation of aminoacyl-tRNA); these MSAs occur in 16% to 26% of patients with IIM.^{2,53} The most common of these is the anti-histidyl-tRNA synthetase antibody (anti-Jo-1), which targets histidyl-tRNA synthetase and is found in approximately 20% of patients with polymyositis or dermatomyositis. Other less common MSAs are listed in Table 149.3.⁵⁵ The presence of antisynthetase autoantibodies is associated with a distinct clinical phenotype, so-called *antisynthetase syndrome*, characterized by interstitial lung disease as the most prevalent clinical manifestation, myositis, arthritis, fever, Raynaud phenomenon, and roughened skin over the lateral and palmar surfaces of the index fingers, termed *mechanic's hands*.²

Anti-signal recognition particle (anti-SRP) autoantibodies are associated with a treatment-resistant myopathy and histopathologic features that include pronounced muscle fiber necrosis and little or no inflammation, termed *necrotizing myopathy*.⁵⁵ The clinical features associated with anti-Mi-2 antibodies are the typical skin rashes of dermatomyositis: Gottron papules, heliotrope rash, and a rash on the upper chest and shoulders—the so-called V-sign and shawl sign; this type has a good prognosis.^{2,55} Another autoantibody associated with dermatomyositis in both adults and children is directed against TIF-1 γ (a p155/p140 protein) and confers a high risk of malignancy in adult patients as mentioned earlier.^{24,55} Yet another novel autoantibody, anti-melanoma differentiation-associated gene 5 (anti-MDA5, or anti-CADM-p140, the clinically amyopathic dermatomyositis p140

antibody), has been found in about 20% of patients with clinical amyopathic myositis and is associated with rapidly progressive interstitial lung disease.⁵⁵ The anti-small ubiquitin-like modifier activating enzyme 1 (anti-SAE-1) antibody is also associated with dermatomyositis, characterized by severe skin involvement and interstitial lung disease.⁵⁵

The strong association between MSAs and distinct clinical features, as well as distinct HLA class II genotypes, implies a role for these autoantibodies in the pathogenesis of these subsets of myositis. However, some unanswered questions remain: First, how could these autoantigens, which are ubiquitously expressed intracellular proteins, elicit an immune response? And second, why are these autoantibodies associated with clinically distinct phenotypes? A few interesting possibilities regarding how these autoantigens could contribute to the immune response and the distinct clinical phenotypes have been suggested recently. The first comes from a demonstrated variation in autoantigen expression between tissues. An increased expression of the myositis autoantigens Mi-2 and histidyl-tRNA synthetase was recorded in regenerating muscle fibers compared with differentiated fibers, which suggests regenerating muscle fibers as a source of antigen in autoimmune myositis.⁵⁶ Some quantitative tissue variations in histidyl-tRNA synthetase expression were also observed, with a higher expression in normal lungs than in other healthy organs, which could possibly explain the frequent lung involvement associated with anti-histidyl-tRNA synthetase (anti-Jo-1) antibodies.

A second possibility is suggested by the interesting observation that the aminoacyl-tRNA synthetases targeted by the immune response in myositis may acquire chemotactic properties.⁵⁷ A possible role *in vivo* could be that these autoantigens may be exposed to the immune system during tissue damage and then act as chemokines to attract immune cells to aid repair as part of the innate immune response. In addition, sera from patients with anti-Jo-1 antibodies may induce type I interferon activity as in systemic lupus erythematosus, which also could be an important mechanism for a sustained immune reaction.⁵⁸

A third possibility relates to the hypothesis that autoantibodies are directed against modified self-proteins. Such modifications could occur during cell death or as a consequence of local inflammation. One such modification occurs through cleavage of proteins by granzyme B, a serine protease that is released by cytotoxic lymphocytes to kill virus-infected cells and tumor cells. Histidyl-tRNA synthetase (Jo-1 antigen) becomes immunogenic after cleavage by granzyme B.⁵⁹ This feature unifies a majority of autoantigens in myositis. Whether the granzyme B/perforin pathway has a role in the immune response *in vivo* in myositis still needs to be clarified.

Accumulating evidence thus suggests that MSAs have a role in the pathogenesis of myositis. However, to date it is not known whether these events are primary in the pathogenesis of disease or rather represent secondary phenomenon occurring as a consequence of tissue inflammation or damage.

INCLUSION BODY MYOSITIS

In inclusion body myositis there are specific features such as the rimmed vacuoles and inclusions of β -amyloid protein that have been the subject

Fig. 149.8 Protein synthesis showing some of the targets of myositis-specific autoantibodies. Several of the myositis-specific autoantibodies target ubiquitous cytoplasmic antigens involved in protein synthesis—for example, the aminoacyl–transfer RNA (tRNA) synthetases—which are important enzymes that bind an amino acid to its tRNA. The ribosomes facilitate the linking of amino acids to form a polypeptide through binding of the tRNAs to messenger RNA (mRNA) templates (translation). This can take place in the cytosol or in the membrane of the endoplasmic reticulum (ER). Another target antigen, signal recognition particle (SRP) is essential for protein translocation across the membrane of the ER. GTP, guanosine triphosphate.

TABLE 149.3
Myositis-specific autoantibodies and their associated disease features

Autoantibody	Autoantigen	Prevalence in IIM (%)	Clinical association	HLA class II alleles
Antisynthetases				
Anti-Jo-1	HisRS	15-40	Antisynthetase syndrome [†]	DRB1*0301, [‡] DQB1*0201, [§] DQA1*0501, [‡] and/or DQA1*0401 [‡]
Anti-PL-7	ThrRS	<5	Antisynthetase syndrome [†]	
Anti-PL-12	AlaRS	<5	Antisynthetase syndrome [†]	
Anti-OJ	IleRS	<5	Antisynthetase syndrome [†]	
Anti-EJ	GlyRS	<5	Antisynthetase syndrome [†]	
Anti-Zo	PhenylRS		Antisynthetase syndrome [†]	
Anti-KS	AspRS		Antisynthetase syndrome [†]	
Anti-HA	ThyRS		Antisynthetase syndrome [†]	
Anti-SRP	SRP proteins	<5	Necrotizing myopathy	DR5, DQA1*0301, DRw52
Anti-KJ	Unidentified protein	<1	Interstitial lung disease	?
Anti-Mi-2	Nuclear helicase	<10	Classic dermatomyositis	DRB1*07, DQA1*0201
Anti-TIF-1γ (p155/140)	TIF-1γ		Juvenile dermatomyositis and dermatomyositis associated with malignancy	
Anti-MDA5 (CADM-140)	MDA5)	20% of CADM	Clinical amyopathic dermatomyositis, rapidly progressive interstitial lung disease	
Anti-SAE	SAE, A and B subunits		Dermatomyositis with interstitial lung disease	
Anti-p140	NXP-2—nuclear transcription	20% of JDM cases	JDM	
Anti-HMG-CoA reductase (anti-200 kDa/100 kDa)	HMG-CoA reductase		Statin-induced necrotizing myopathy	

[†]Antisynthetase syndrome is interstitial lung disease, fever, arthritis, Raynaud phenomenon, and mechanic's hands.
[‡]In black and Mexican American patients.
[§]In white patients.
^{||}Linked alleles.
Ala, alanyl; Asp, asparaginy; DM, clinical amyopathic dermatomyositis; Gly, glycyl; His, histidyl; HLA, human leukocyte antigen; HMG-CoA, hydroxymethylglutaryl-coenzyme A; IIM, idiopathic inflammatory myopathy; Ile, isoleucyl; JDM, juvenile dermatomyositis; MDA5, melanoma differentiation-associated gene 5; Phenyl, phenylalanyl; RS, tRNA synthetase; SAE, small ubiquitin-like modifier activating enzyme 1; SRP, signal recognition particle; Thr, threonyl; Thy, thyranyl; TIF, transcriptional intermediary factor.

of much interest.⁶⁰ Another characteristic of inclusion body myositis is the resistance to immunosuppressive treatment. Although some features are shared with polymyositis and dermatomyositis, as discussed earlier, there still is debate as to whether inclusion body myositis should be regarded as an inflammatory myopathy or as a degenerative myopathy with secondary inflammation.⁶¹ β -Amyloid, one of the degenerative proteins identified in muscle fibers of patients with inclusion body myositis, can stimulate human myoblasts to IL-6 production. This could imply that in muscle tissue of patients with inclusion body myositis there is a continual stimulation of IL-6 production, which could have a proliferative effect on the local immune response. Supporting a role for the humoral immune response at the site of tissue damage in inclusion body myositis is the recent observation that recombinant immunoglobulins reconstructed from single plasma cells derived from inclusion body myositis muscle tissue recognized desmin, a major intermediate filament protein.⁶² The role of the immune response in inclusion body myositis needs further investigation, however.

CONCLUSION

Both cellular and humoral immune mechanisms as well as nonimmune mechanisms are important in the pathogenesis of myositis. Muscle weakness and muscle fatigue, the major clinical features in myositis, could be caused by different mechanisms in different phases of the disease. In early disease the reversible changes that may affect muscle metabolism could play a major role, and in later disease irreversible changes that could be related to muscle fiber damage and replacement of muscle tissue by connective tissue and fat may be predominant factors. On the basis of the findings to date, it is likely that soluble factors such as cytokines, which are produced in muscle tissue by different sources such as inflammatory cells, endothelial cells, and muscle fibers, could affect muscle function and have an important role in pathogenesis. A better knowledge of key molecular pathways and the specific molecules affect muscle function will likely lead to new and more targeted therapies.

Management of inflammatory muscle disease

■ FREDERICK W. MILLER

- A correct diagnosis, which almost always requires a muscle biopsy to rule out noninflammatory myopathies, is central to optimal treatment.
- Therapy for myositis is based more on anecdotal information and custom than on controlled trial data.
- Clinical remission, or elimination of all evidence of disease activity in all organ systems, is a realistic objective for most patients and should be pursued aggressively to optimize outcomes.
- Corticosteroids remain the most effective agents, but they should be supplemented by other drugs early in patients with poor prognostic features.
- For patients with dermatomyositis, sunscreens, sun avoidance, minimizing use of photosensitizers, topical corticosteroids, and hydroxychloroquine (Plaquenil) can be beneficial.
- Methotrexate and azathioprine are the most frequently used corticosteroid-sparing agents.
- Mycophenolate, cyclosporine, tacrolimus, cyclophosphamide, intravenous gamma globulin, anti-tumor necrosis factor agents, and rituximab are of benefit in some patients who do not respond to methotrexate or azathioprine.
- Most patients benefit from a graded rehabilitation program instituted as early as possible.
- Treatment of inclusion body myositis is unsatisfactory and controversial.
- Therapy needs to be individualized to the type of myositis, medical history, level of disease activity and disease damage, expectations, prognosis, and risk for adverse events in each patient.

GENERAL PRINCIPLES

The rarity and heterogeneity of the idiopathic inflammatory myopathies (IIMs), along with the few validated assessment tools, have limited the controlled trial data available to guide therapy and management. Few agents have been approved by the Food and Drug Administration for use in patients with myositis, and therapy remains challenging even for expert myologists. Nonetheless, a number of case series, some open-label trials, and a few randomized controlled studies have been performed in small groups of patients and can guide aspects of therapy (Table 150.1).¹⁻²⁵

The primary goal in the management of myositis is to improve function to as close as possible to the patient's predisease state. This is accomplished by (1) making an accurate diagnosis; (2) educating patients and their families about myositis; (3) defining and addressing patients' and families' major concerns; (4) enumerating the prognostic risk factors; (5) defining the extent of disease activity and disease damage in all affected systems; and (6) developing, with the patient's input, an individualized management approach that incorporates all of the above, as well as the patient's expectations and risk factors for adverse events with therapy. It is useful to think of the management of myositis in terms of that used for cancer patients, with initial induction therapy to rapidly decrease inflammation and achieve remission and later maintenance therapy to minimize the chance for relapse. Expert opinion is developing that in most cases, clinical remission, which is elimination of all evidence of disease activity in all organ systems, is a realistic objective and should be pursued aggressively to optimize outcomes.

Ensuring an accurate diagnosis is critical to all other aspects of management because there are so many mimics of the inflammatory myopathies

(see Chapter 148) and the therapeutic approaches differ greatly for many of them. Patients who were referred without an appropriate diagnostic evaluation, those who are not responding to adequate immunosuppressive therapy within the first several months, and those with atypical features should be reevaluated carefully to ensure a correct diagnosis. An important aspect of management involves the education of patients and their families about their disease (see "Additional Resources for Patients and Physicians").

Poor prognostic factors for myositis are not well defined, but a number of features have been suggested, as listed in Box 150.1.²⁶⁻²⁸ Despite few controlled studies to support a more aggressive approach in patients with poor prognostic factors, anecdotal information suggests that for those with poor prognostic features, adding additional immunosuppressive therapy to corticosteroids early in the disease course may improve outcomes.^{29,30} It is important to determine all the organ systems involved in these systemic disorders and to assess the degree of disease activity and damage that is present in each, and newly developed tools are useful in capturing this information.³¹ Integrating this information into a cohesive whole is the most difficult part of developing a comprehensive treatment strategy for patients with myositis. This should include an understanding of the expectations of the patient, as well as possible risk factors for adverse events with the therapies being considered.

Different groups of patients with myositis appear to have various degrees of disease activity at onset and to respond differently to therapeutic agents over time.^{26,32} Figure 150.1 presents the general disease courses for the major clinicopathologic and autoantibody groups of myositis and emphasizes that in certain groups of patients, disease activity is more likely to increase after reducing medications—for these groups, medications should be tapered more carefully.

Most of the focus of this chapter is on adult-onset IIM, but similar approaches should be considered for juvenile-onset disease and in those with dermatomyositis (DM) without significant muscle involvement (DM sine myositis).^{33,34}

PRIMARY DRUG THERAPIES

Even though just limited anecdotal information is available to guide therapy and no consensus has been reached on the best approaches, an algorithm for the treatment of inflammatory myopathies based on common clinical practices is proposed in Figure 150.2.

Corticosteroids

Daily oral corticosteroids are the primary initial therapy used to treat myositis. Despite the lack of controlled studies to support this practice, they are considered by most investigators to be the most effective treatment of polymyositis (PM) and DM.²⁷ Although the majority of patients have at least a partial response to corticosteroids, many do not respond adequately, many more experience increases in disease activity during steroid tapering, and most eventually suffer from the toxicities of corticosteroids. The initial dose and route of administration of corticosteroids are usually determined by disease severity, the number of poor prognostic factors present, and the risk factors for adverse events in each patient. A common practice is to begin with prednisone at 1 to 2 mg/kg/day. Prednisone is often begun as a single daily dose to minimize adverse effects; however, if an inadequate response is seen, it is frequently changed to a divided daily dose.

In patients with severe myositis and those with significant active pulmonary, cardiac, or gastrointestinal disease or other poor prognostic features, intravenous methylprednisolone 1 g/day for 3 consecutive days may be used

Idiopathic inflammatory myopathy: management and prognosis. *Rheum Dis Clin North Am* 2002;28:979-1001; and Mastaglia FL, Zilko PJ. Inflammatory myopathies: how to treat the difficult cases. *J Clin Neurosci* 2003;10:99-101.

to achieve a more rapid response and avoid any question of inadequate oral adsorption. How rapidly to decrease the corticosteroid dose is determined by the patient's clinical response to therapy. A common error is to attempt too rapid a decrease in dose, which often results in increased disease activity requiring another course of higher-dose corticosteroids. The dose at which a disease flare occurs is fairly constant and predictable for a given patient.³⁵ To minimize the chance of disease flares during tapering, some investigators suggest maintaining an initial dose of prednisone at 1 mg/kg/day for at least a month and until the creatine kinase (CK) level returns to

GENERALIZED DISEASE COURSES FOR CLINICAL AND AUTOANTIBODY GROUPS OF MYOSITIS PATIENTS

Fig. 150.1 Patients with myositis in association with other connective tissue diseases (myositis overlap) tend to have milder myositis that responds relatively well to therapy and infrequently return after withdrawal of therapy when compared with those with dermatomyositis. Polymyositis patients have more severe disease at onset with poorer responses to therapy and frequent exacerbations after tapering therapy. Patients with inclusion body myositis have slowly progressive disease that tends to be unresponsive, but some patients have the possibility of slowing of the rate of deterioration with therapy. A similar difference in myositis severity at onset, response to therapy, and disease exacerbation with withdrawal of therapy is seen in the serologic groups; patients with anti-Mi-2 autoantibodies have the best prognosis, followed by the antisynthetase and finally the anti-signal recognition particle (SRP) antibody groups. (Modified from Plotz PH, Rider LG, Targoff IN, et al. NIH conference. Myositis: immunologic contributions to understanding cause, pathogenesis, and therapy. *Ann Intern Med* 1995;122:714-24.)

normal and then reducing the prednisone dose by 25% monthly to a maintenance dose of 5 to 10 mg/day.²⁷ Other approaches include changing the prednisone to an alternate-day regimen once disease control has been achieved. There are few data to suggest how long corticosteroid maintenance therapy should continue after the initial clinical response and normalization of CK levels. A conservative approach is to continue with prednisone at 5 to 15 mg/day for a period of 6 months after achieving clinical remission.

Prolonged high-dose corticosteroid treatment should be avoided to minimize adverse effects and optimize outcomes. The many adverse events from

prolonged high-dose corticosteroid use include osteoporosis with vertebral collapse and osteonecrosis, hypertension, hyperglycemia, Cushing syndrome, cataracts, more frequent infections, and steroid myopathy. Patients must be advised about these potential problems and be evaluated carefully for their development at follow-up visits. Regarding steroid-induced myopathy, patients in whom increasing weakness develops while taking high-dose corticosteroids, with other evidence of decreasing disease activity, should be considered for empirical reductions in the corticosteroid dose. Calcium and

vitamin D supplements and bisphosphonates should be prescribed for those being treated long-term with corticosteroids.

Other agents

Even though previous approaches involved reserving additional immunosuppressive agents for those who failed corticosteroid therapy or had intolerable adverse effects, initial use of cytotoxic agents along with corticosteroids in patients with poor prognostic features is becoming more frequent. This more aggressive strategy has the advantage of minimizing the adverse effects of corticosteroids and offering the possibility of better outcomes in those who would otherwise be predicted to not do well.^{36,37}

Methotrexate

Because of its extensive history, safety record, and anecdotal efficacy, methotrexate is considered by many investigators to be the first choice as corticosteroid-sparing therapy for patients with inflammatory myopathy.²⁷ Retrospective data suggest that responses to methotrexate usually occur within 2 to 3 months and are better in men and those with antisynthetase syndrome.³⁵ A common practice is to begin dosing at 10 to 15 mg/wk and increase the dose by 5 mg/wk every month to a maximum of 25 to 30 mg/wk as needed. For those in whom gastrointestinal intolerance develops or adequate oral absorption is uncertain, subcutaneous administration may be used. The combination of methotrexate and azathioprine might benefit some patients who had not shown adequate responses to either agent alone.⁸

BOX 150.1 POOR PROGNOSTIC FACTORS IN INFLAMMATORY MYOPATHIES*

Older age at onset
Delay until diagnosis and treatment
Severe myositis
Significant pulmonary, cardiac, or gastrointestinal involvement
Previous lack of response to immunosuppressive therapy
Polymyositis versus dermatomyositis
Cancer-associated myositis
Inclusion body myositis
Antisynthetase, anti-signal recognition particle (SRP), anti-155/140, and anti-CADM-140 autoantibodies

*Information derived from references 26-28.

Fig. 150.2 CK, creatine kinase; IV, intravenous; IVIG, intravenous immunoglobulin; MRI, magnetic resonance imaging; STIR, short tau inversion recovery; TNF, tumor necrosis factor.

The primary toxicities of methotrexate, which are dose related, are gastrointestinal intolerance, fatigue or malaise for several days after the dose, cytopenia, and hepatic toxicity. The latter can be difficult to assess in patients with myositis, in whom elevations in serum transaminases and lactate dehydrogenase as a result of myoblast activation are common. Because serum levels of these enzymes usually correlate with serum CK levels, it is often useful to monitor the relative levels or ratios of transaminases and lactate dehydrogenase to CK levels to assess hepatic toxicity.³⁸ Although pulmonary toxicity from methotrexate can occur, it appears to be a less common problem in myositis than in rheumatoid arthritis and is one of the best agents for treating antisynthetase syndrome, in which lung disease is common.³⁹ Frequently, an empirical trial of decreasing or stopping the dose of methotrexate may be needed to fully assess the possible role of methotrexate as a contributor to new or unexplained signs or symptoms.

Azathioprine

Azathioprine is considered to be as effective as methotrexate in managing corticosteroid-resistant myositis, yet the time to response may be longer than that seen with methotrexate.³⁶ The usual effective dose is 150 to 200 mg/day. Controlled studies suggest that azathioprine plus corticosteroids improves functional ability over corticosteroids alone at 1 and 3 years of follow-up.^{2,40} The most frequent adverse effects are gastrointestinal intolerance, leukopenia, and liver toxicity.

Intravenous gamma globulin

Many studies suggest that intravenous gamma globulin (IVIG) is effective in adults and children with DM and PM.^{3,5,41,42} Because of its rapid onset of action and lack of immunosuppression, some experts suggest that IVIG is most useful as bridging therapy in patients with DM and those with severe myositis or serious infections. Studies regarding the use of IVIG for inclusion body myositis (IBM) have generally not shown effectiveness (see [Table 150.1](#)). Although a variety of doses have been used, a common approach is to give 1 g/kg/day for 2 consecutive days every month for a 3- to 6-month period.

Difficulties associated with the use of IVIG include its high cost, occasional scarcity, tachyphylaxis, and variations in effectiveness from lot to lot. Side effects include headaches, aseptic meningitis, flulike symptoms, rash, changes in blood pressure, and occasional thrombosis related to high blood viscosity. Many of these problems can be minimized by ensuring good patient hydration and slowing the rate of infusion of IVIG.

Mycophenolate

Small case series suggest that some patients with corticosteroid-resistant PM or DM respond to mycophenolate mofetil,^{43,44} although many myologists would use this agent after trials of methotrexate and azathioprine. Common starting doses are 500 mg twice per day, and this dosage may be titrated up to 1 g twice per day. Improvements in CK levels and strength often occur within 1 to 2 months. Side effects include gastric discomfort, diarrhea, cytopenia, and an increased rate of infections.

Cyclophosphamide

Cyclophosphamide appears to be less effective and more toxic than methotrexate or azathioprine when used for myositis, but it may be useful in patients with vasculitis and interstitial lung disease (ILD).^{23,27} Oral doses of 1 to 2 mg/kg/day, not to exceed 150 mg/day, are often prescribed. Monthly pulsed intravenous therapy may be helpful for ILD, as discussed later.

Cyclosporine/tacrolimus

Cyclosporine and tacrolimus work in similar ways to inhibit activation of CD4+ T cells. Small case series suggest that some corticosteroid-resistant adult and juvenile patients may benefit from cyclosporine or tacrolimus therapy.²⁷ Difficulties with the use of these drugs include interactions with grapefruit juice and other agents that influence their metabolism, a wide range of adverse effects, and a narrow therapeutic window that requires careful monitoring of drug levels.

OTHER DRUG THERAPIES

Antimalarials

Based on extensive anecdotal experience, antimalarials have been used for decades in children and adults with primary DM, DM sine myositis, and cancer-associated DM.⁴⁵ About a third of patients with DM may have an exacerbation of their skin disease after initial treatment, but this may resolve over time with continued treatment. Clinical experience suggests that in

patients with IIM, other nonmuscular manifestations of disease, including arthritis, fatigue, and subcutaneous inflammation (panniculitis), may benefit from antimalarial therapy. Most clinical reports involve hydroxychloroquine, usually given at 200 to 400 mg/day, but chloroquine and quinacrine have also been used with some benefit. One small case series suggested that some DM patients whose skin lesions have been unresponsive to a single antimalarial benefit from combination therapy consisting of hydroxychloroquine and quinacrine or chloroquine and quinacrine.⁴⁶

Anti-tumor necrosis factor agents

Infliximab has been reported to benefit some children with DM, as well as some adults with DM and PM; however, open-label trials have not been promising. One open-label trial of infliximab in 13 patients with PM, DM, or IBM resulted in 9 patients completing the 14-week study. Of these, three improved, four were unchanged, and two significantly worsened, thus suggesting to the authors that infliximab is not useful for treatment-resistant myositis.²⁵ Another open-label trial in patients with PM or DM treated with anti-tumor necrosis factor- α (TNF- α) and concurrent methotrexate therapy was discontinued prematurely because of a low inclusion rate and a high dropout rate as a result of disease progression and the development of an infusion reaction.⁴⁷ An open-label trial of etanercept in nine patients with IBM showed no evidence of improvement.²²

Concerns regarding anti-TNF agents as therapy for PM/DM include case reports of the development of myositis during their use for other diseases, as well as exacerbation of myositis after their use for established myositis.⁴⁸ Given the current data, more study is needed to determine the role of anti-TNF agents for myositis.

Rituximab

A number of case reports and case series of adult and children with DM and PM have reported positive responses to rituximab.^{13,49,50} In some cases retreatment has also resulted in positive responses. A recent large placebo phase design clinical trial did not show efficacy based on the primary end point, yet 83% of patients met the definition of improvement suggesting the usefulness of this agent.^{50a} Overall, little toxicity has been reported with this therapy.

Other agents

A variety of other treatments have been reported, usually in small numbers of myositis patients, with limited or no evidence that they are useful. Such therapies include apheresis, with a negative controlled trial in patients with PM/DM⁵¹; fludarabine, with some evidence of response in several patients in a pilot open-label trial of PM/DM⁵²; interferon beta, with two negative trials for IBM^{20,21}; total body irradiation, with several positive and several negative case reports in patients with PM, DM, and IBM; and case reports of responses to autologous stem cell transplantation, thymectomy, chlorambucil, alemtuzumab, extracorporeal photopheresis, or leflunomide for PM or DM.

Few studies have attempted to understand how to best combine the many immunosuppressive agents often used to treat myositis. One open-label trial suggested that combination methotrexate and azathioprine may be of benefit in patients who had not responded adequately to either agent alone.⁸ Given the complementary modes of action of many agents, this should be a promising area of research in the future.

NONMEDICAL TREATMENTS

Patient and family education

Optimal therapy is based on patients thoroughly understanding their disease. Patients and their families should be counseled and educated about myositis. Understanding the social and work environment of patients will also assist in best helping them adjust to their disease. Referrals to local and national myositis patient support groups should be made because they can be invaluable sources of information and support (see [“Additional Resources for Patients and Physicians”](#)).

Rehabilitation

A primary goal of therapy is to optimize the functional capacity of patients.²⁹ Rehabilitation is a critical aspect of this goal, yet it remains underused by most physicians and patients.⁵³ Graded rehabilitation that takes into account

BOX 150.2 AN APPROACH TO REHABILITATION OF PATIENTS WITH MYOSITIS**Acute phase—assess the patient for the possible needs below**

Massage and heat treatment of painful muscles.
 Fit with an appropriate collar for neck support.
 Use a balanced forearm orthosis on the wheelchair so that some independent feeding is possible.
 Support the wrists and ankles with resting splints to prevent flexion contractures.
 Instruct the patient in the use of a long-handled comb and toothbrush and a sponge to assist in self-care.
 Regular evaluations and treatment by a speech and language pathologist arranged as needed.
 Nurses and family should be trained in proper bed positioning, the appropriate position to facilitate feeding and prevent aspiration, techniques to facilitate breathing, and bed-to-chair transfers as needed.

Early recovery phase—assess the patient for the possible needs below

Begin muscle reeducation and strengthening.
 Give instructions in active range-of-motion exercises and begin a few isometric contractions of the major muscle groups (deltoids, biceps, quadriceps, hip abductors/extensors).
 Work on standing at the parallel bars and begin ambulation training.
 Occupational therapy as needed for dressing and bathroom care with appropriate bathroom devices (elevated toilet seat, bars, shower chair, hand-held shower).
 Assess vocational abilities and advise on-the-job retraining if necessary.
 As balance improves and strength becomes good (4/5 range), ambulation with only a straight cane can be initiated; some pelvic lurching may still be present because of gluteus medius muscle weakness, and the gait will be slow; work on negotiating stairs and ramps and practice walking outdoors, as well as car transfers.
 As enzyme levels decrease, increase the isometric exercise program to six contractions of each muscle group daily; pool therapy with range-of-motion and stretching exercises is permitted.
 Help the patient incorporate energy conservation strategies into the day.

Late recovery and chronic phase—assess the patient for the possible needs below

Isotonic exercise with low weights (2 to 4 kg) or a pool.
 Bicycle ergometry without resistance or walking in a pool or swimming.
 Gradual aerobic exercise (starting with 15-minute sessions and increasing to 30-minute sessions three times weekly).

the stage and severity—of the patient's disease is the optimal approach (Box 150.2). Although bed rest may be necessary during periods of severe myositis, even then passive range-of-motion exercises and stretching should be initiated to minimize or prevent the formation of contractures. Massage and heat treatment of painful muscles, collars, splints, or braces for support and assistive devices for self-care are often helpful. As patients respond to treatment, they should increase their activity through four stages: active assisted range-of-motion, followed by isometric, then isotonic, and finally aerobic exercise. If this graded approach is followed, there is little chance of disease flares developing.

ASSESSING DISEASE ACTIVITY AND DAMAGE

An important element in choosing appropriate therapy and monitoring responses to therapy for chronic systemic diseases such as myositis is careful assessment of all the disease manifestations over time. This includes determination of the type and degree of disease activity (evidence of active inflammation that is potentially reversible) and disease damage (persistent changes, including scarring and fibrosis that develop from previous active disease or complications of therapy) in all affected organ systems, and a number of tools have been developed for these purposes.³¹

Evidence of disease activity includes active rash; arthritis; elevation of serum CK, other muscle enzymes, or immunoglobulin levels; and recent alterations in muscle strength or function, energy level, muscle tenderness, dyspnea, or dysphagia. Evidence of disease damage includes joint contractures, muscle atrophy, hyperpigmentation or hypopigmentation, calcifications, and decreased serum creatinine.

The most common way of assessing disease activity and responses to therapy is to monitor serum CK, lactate dehydrogenase, or other muscle enzyme levels and muscle strength by manual muscle strength testing (Table 150.2). Because elevated muscle enzymes do not develop in some patients during periods of active disease and because disease activity in all organ

TABLE 150.2**Manual muscle strength testing grades**

0	No muscle contraction
1 (trace)	Palpable contraction, little or no motion
2 (poor)	Motion possible but not against gravity
3 (fair)	Motion against gravity possible
4 (good)	Motion possible against natural resistance
5 (normal)	Motion possible against considerable manual resistance

systems does not change over time in similar ways, other more comprehensive approaches have recently been developed. One way to systematically assess myositis disease activity and damage is through the use of core set measures and tools validated by the International Myositis Assessment and Clinical Studies Group (IMACS, available at <http://www.niehs.nih.gov/research/resources/imacs/abouttools/index.cfm>).⁵⁴ Although these approaches were developed for use in clinical trials, they also provide a comprehensive and sensitive way of tracking changes in clinical and laboratory parameters over time in the practice setting. The core set disease activity measures are patient and physician global assessment, manual muscle strength testing, serum levels of muscle enzymes, the health assessment questionnaire, and the myositis disease activity assessment tool. Significant clinical improvement can be defined as improvement of 20% or greater in three of any six of these core set measures, with no more than two becoming worse by 25% or greater (which cannot include manual muscle testing to assess strength).⁵⁵ Disease damage over time can be assessed in similar ways with the Myositis Damage Index.

Magnetic resonance imaging (MRI) of the thighs can be useful in long-standing cases to quantitate the degree of disease activity and damage in muscle, skin, and subcutaneous tissue. Bright signals on short tau inversion recovery (STIR) MRI represent increased water content, which is related to active inflammation, whereas bright signals on T1-weighted MRI represent fatty replacement. The T1 image also allows quantitative assessment of the degree of muscle atrophy present.

MANAGEMENT OF EXTRAMUSCULAR MANIFESTATIONS**Interstitial lung disease**

ILD develops in 30% to 40% of patients with PM/DM, is a major cause of morbidity and mortality, and is one of the most difficult myositis manifestations to assess and treat. ILD is most commonly seen in IIM patients with antisynthetase autoantibodies (see Chapter 149), and these patients may be more likely than ILD patients without autoantibodies to respond to therapy. Progression of ILD in patients with myositis may be acute, subacute, or chronic. Various approaches have been reported to be helpful in these patients, including high-dose intravenous corticosteroids, intravenous cyclophosphamide, cyclosporine, and tacrolimus.⁵⁶ Sequential follow-up examinations consisting of pulmonary function testing, high-resolution computed tomography of the chest, and careful monitoring for bacterial and viral infections are essential.

Cardiac involvement

Subclinical cardiac involvement is common with myositis, although it may not come to clinical attention unless symptomatic cardiac failure or arrhythmias occur. If these problems arise, myocarditis should be suspected and may be assessed by clinical measures and evaluation of serum troponin I levels. Because serum troponin T and CK-MB levels can be elevated as a result of activated myoblasts, they are better measures of disease activity than measures of cardiac involvement. Treatment of cardiac manifestations includes supportive care along with corticosteroids and other immunosuppressive therapy, depending on the severity of involvement.

Gastrointestinal involvement

Dysphagia, gastroesophageal reflux, abdominal bloating, and constipation or diarrhea are common problems in patients with myositis.

Severe dysphagia may lead to aspiration and requires careful evaluation and aggressive therapy with pulse corticosteroids, IVIG, and other immunotherapy. Cricopharyngeal myotomy or percutaneous gastrostomy tube feeding may be needed in severe cases.

Reflux esophagitis is a frequent complication with myositis and should be treated by the usual approaches of elevating the head of the bed and prescribing antacids or H₂-receptor antagonists. An unusual but life-threatening complication seen more commonly in children with DM is mucosal ulceration or perforation of the lower gastrointestinal tract from active vasculitis. This can lead to severe hemorrhage and secondary infections and often requires emergency surgery and aggressive treatment with high-dose intravenous corticosteroids, IVIG, and cytotoxic therapy.

Skin involvement

Myositis is associated with a wide variety of cutaneous manifestations that range from asymptomatic rash to life-threatening vasculitis and ulcerations (<http://dermatology-s10.cdlib.org/1502/reviews/photoessay/riderphotos.html>). Many DM skin lesions are photosensitive and respond at least partially to first-line treatments, such as avoidance of ultraviolet radiation and photosensitizers and the use of sunscreens or topical corticosteroids. Antimalarials are often the next therapy to consider for rash that does not respond to first-line treatment. Topical tacrolimus and systemic corticosteroids, methotrexate, mycophenolate, and IVIG have all been reported to be useful in treating the more severe skin lesions of DM.⁵⁷

Calcinosis

The best treatment of calcinosis is prevention through aggressive evaluation and treatment of skin and subcutaneous disease and avoidance of trauma. Once established, no therapies have proved to be effective, although some investigators have proposed the use of calcium channel blockers, vitamin K inhibitors, aluminum hydroxide, or colchicine. In severe cases in which the lesions produce chronic pain or impinge on critical structures, surgical removal may be necessary. When calcinosis lesions push out through the skin surface, they may drain “milk of calcium” and are at risk for infection (<http://dermatology-s10.cdlib.org/1502/reviews/photoessay/rideressay.html>).

Inclusion body myositis

Treatment of IBM is controversial and unsatisfactory. Some investigators do not think that immunosuppressive therapy is helpful for IBM. Nonetheless, anecdotal reports and retrospective reviews of corticosteroid and cytotoxic therapy, a prospective open-label trial of IVIG, and a randomized trial of combination oral methotrexate plus azathioprine versus high-dose methotrexate with leucovorin rescue all provide limited evidence that the rate of functional deterioration may be decreased or stabilized and strength

improved in a subset of patients with IBM (see [Table 150.1](#)). Characteristics that may identify those with IBM more likely to respond to immunosuppressive treatment are serum CK levels greater than five times the upper limit of normal, active inflammation noted on MRI or muscle biopsy, disease overlapping with other connective tissue diseases, and the presence of autoantibodies. Physical therapy and exercise, however, play the most important roles in the long-term care of patients with IBM.

FUTURE DIRECTIONS

Appropriately powered and long-term multicenter trials using validated outcome measures are needed to define the best treatment options for the IIMs. Given the growing number of distinct myositis phenotypes, each with probably different pathogenesis and response to therapy, it will be increasingly important to study these well-defined subgroups individually. Recent advances in genetics and molecular biology, the initial definition of environmental risk factors for myositis, novel therapies for other diseases, and new international collaborations and standards all promise the hope of not only inducing prolonged remissions but even the possibility of preventing the development of some cases of myositis in the future.

Metabolic, drug-induced, and other noninflammatory myopathies

■ GEORGE STOJAN ■ LISA CHRISTOPHER-STINE

- The differential diagnosis of polymyositis and other inflammatory myopathies includes metabolic disorders and drug- or toxin-induced myopathies in addition to endocrine disorders, muscular dystrophies, and infectious etiologies.
- The primary metabolic myopathies are inherited disorders of muscle glycogen, lipid, or mitochondrial metabolism; they may cause episodic exercise intolerance along with myoglobinuria or progressive proximal muscle weakness.
- Drugs and toxins can induce myopathies through direct toxic effects on muscle, induction of autoimmune-mediated inflammatory myopathy, or metabolic derangements.

METABOLIC MYOPATHIES

Muscle contraction and relaxation are energy-dependent processes that derive energy from the hydrolysis of adenosine triphosphate (ATP). The supply of ATP is crucial, and several pathways have evolved, with each supplying energy under specific conditions to ensure a continuous supply of energy under a variety of circumstances. The processes responsible for maintaining a continual supply of ATP include glycogen and glucose metabolism, oxidative phosphorylation, the creatine kinase (CK) reaction by which phosphocreatine is converted to ATP, the purine nucleotide cycle, and lipid metabolism.¹

Glycogen/glucose metabolism (Fig. 151.1)

Anaerobic glycolysis is the main metabolic pathway used in the setting of limited oxygen supply during exercise. It is used during high-intensity, sustained, isometric muscle activity.¹ It is inefficient from an energetic standpoint and produces only two ATP molecules per glucose molecule, which is 19 times less than the full energy potential of a glucose molecule. Despite its inefficiency, it is a rapid process, approximately 100 times faster than oxidative phosphorylation. The final step in the pathway is conversion of pyruvate to lactate, which leads to accumulation of lactic acid.

Aerobic glycolysis is more efficient; however, the price needed to maintain this system is high: it requires functional mitochondria, a functioning circulatory system with a constant oxygen supply, and the ability to eliminate carbon dioxide. It is used as the main supply of energy during sustained, dynamic forms of exercise such as walking, but if short bursts of energy are needed, the system is often overwhelmed and anaerobic glycolysis takes over.

The phosphocreatine pathway acts as a “buffer” of ATP stores by limiting changes in ATP and allowing rapid formation of ATP during high-intensity exercise. The amount of phosphocreatine in muscle is small, and it is not able to sustain activity independently.

ATP can also be produced by the adenylate kinase reaction, which catalyzes the conversion of two adenosine diphosphate (ADP) molecules into one ATP and one adenosine monophosphate (AMP); however its clinical significance is limited.

The oxidative phosphorylation system (Fig. 151.2), present in the inner mitochondrial membrane, is the principal source of energy in muscle and other tissues. The flow of electrons from the reduced form of nicotinic adenine dinucleotide (NADH) to the last enzyme in the electron transport chain, cytochrome-c oxidase (complex IV), releases energy that is used in the synthesis of ATP.

Lipid metabolism

The major energy substrates used by resting muscle are fatty acids derived from very-low-density lipoprotein (VLDL) or from stored triglycerides. The metabolism of short-, medium-, and long-chain fatty acids is slightly different, yet these biochemical details have great clinical relevance.

Long-chain fatty acids are the major source of energy for prolonged, low-intensity exercise lasting longer than 40 to 50 minutes.¹ Unlike short- and medium-chain fatty acids, they are not able to freely cross the mitochondrial membrane and need to undergo a series of modifications. The first step is their conversion to coenzyme A (CoA) thioesters, which are then linked to carnitine by the enzyme carnitine palmitoyltransferase I (CPT-I), located on the inner side of the outer mitochondrial membrane. A translocase then transfers the acylcarnitine product across the inner mitochondrial membrane. Once in the mitochondrial matrix, CPT-II is required to convert the acylcarnitine molecule back into a CoA thioester and carnitine. Only then can the long-chain fatty acid derivative enter the β -oxidation pathway.

Short-chain and medium-chain fatty acids have a much less convoluted metabolic fate because they cross the mitochondrial membranes without difficulty and enter the β -oxidation pathway directly after activation to CoA thioesters. With each cycle of β -oxidation, a two-carbon fragment is cleaved and one acetyl-CoA molecule is generated. The acetyl-CoA then enters the citric cycle.

Part of the acetyl-CoA produced in the liver is used for ketone production at baseline. During periods of carbohydrate deprivation or fasting, ketone production is upregulated and it becomes an important source of energy for many tissues, including the brain.

General principles

The substrate used by muscle depends on the type of activity. Fatty acids are the predominant energy source at rest, whereas intense bursts of exercise will activate anaerobic glycolysis.² Mild exercise will initially use aerobic glycolysis but, if sustained, will gradually switch to fatty acid oxidation as the main energy source after 4 hours. Submaximal exercise of low intensity will use both glucose and fatty acids, and high-intensity exercise will use mainly aerobic glycolysis.^{3,4}

The metabolic myopathies are characterized, in general, by dynamic rather than static findings. This means that the symptoms and signs are usually triggered by activity. The most common phenotypes are exercise intolerance, exercise-induced weakness and muscle cramps, and only rarely, progressive, fixed weakness.¹ Importantly, patients with exercise-induced symptoms may not have any evident signs of muscle disease, such as weakness or muscle atrophy, and may have normal findings on electromyography (EMG) and routine laboratory values.

The diagnostic approach to the metabolic myopathies includes blood tests (serum CK [Box 151.1], lactate, ammonia, acylcarnitine, and amino acid profile), urine tests (organic acids and myoglobin), muscle biopsy (light and electron microscopy and biochemical assays), EMG, exercise testing, genetic testing, and magnetic resonance imaging (MRI).⁵ Before proceeding with expensive or invasive diagnostic modalities such as genetic testing and muscle biopsy, simple exercise tests may be used for screening purposes.

The ischemic forearm exercise test is a highly sensitive and specific diagnostic screening test for muscle glycolytic disorders. The protocol involves inflating a blood pressure cuff on the upper part of the arm to 20 mm Hg higher than systolic blood pressure. The patient is given a hand-grip dynamometer and told to squeeze it at maximum strength for 1 second followed by 1 second of rest. The cuff is released immediately after exercise. Blood samples from the tested arm are drawn at rest, during exercise, and

PATHWAYS OF CYTOSOLIC GLYCOGEN METABOLISM

Fig. 151.1 Deficiencies in the numbered enzymes are recognized to cause a glycogen storage disease: 1, phosphorylase b kinase; 2, brancher enzyme; 3, myophosphorylase; 4, debrancher enzyme; 5, phosphofructokinase; 6, aldolase A; 7, phosphoglycerate kinase; 8, phosphoglycerate mutase; 9, β -enolase; 10, lactate dehydrogenase. Note that acid maltase is not included because it is a lysosomal enzyme. P, phosphate; PLD, phosphorylase limit dextran; UDPG, uridine diphosphate glucose.

during recovery, and blood levels of lactate and ammonia are measured.⁶ Normal subjects exhibit a threefold to fivefold rise in lactate and ammonia levels within 5 minutes after the end of the exercise, with a return to baseline about 10 to 15 minutes after cessation of the test.

If the lactate and ammonia responses are normal and suspicion for an underlying metabolic or mitochondrial myopathy persists, the next screening step is an aerobic exercise test. Patients with mitochondrial myopathies may have elevated resting lactate levels, but this finding is not universal. Cycle or treadmill ergometry is used to assess the cardiorespiratory response, arteriovenous oxygen difference, and lactate levels. Classically, patients with mitochondrial myopathies exhibit impaired oxygen extraction by the muscle, elevated lactate levels, and an intense cardiorespiratory response to exercise.⁷

BOX 151.1 CAUSES OF ELEVATED SERUM CREATINE KINASE LEVELS IN PATIENTS WITHOUT OVERT MUSCLE DISEASE

- Prolonged physical exercise
- Black race
- Frequent muscle trauma
- Sustained alcohol use
- Hypothyroidism
- Drugs causing subclinical myopathy
- Inflammatory myopathy
- Metabolic myopathy
 - McArdle disease
 - Acid maltase (α -glucosidase) deficiency
 - Phosphorylase b kinase
 - Periodic paralysis
 - Mitochondrial myopathy
- Muscular dystrophy
 - Dystrophinopathy
 - Caplain-3 gene mutation
 - Dysferlin gene mutation
 - Fukutin-related protein mutation
 - Malignant hyperthermia gene

The major categories of metabolic myopathies are defects in glucose/glycogen metabolism, disorders of fatty acid oxidation, mitochondrial diseases, and myoadenylate deaminase deficiency.⁵

Defects in glucose/glycogen metabolism

Depending on the specific enzyme deficiency, defects in glucose and glycogen metabolism can result in protean manifestations ranging from lethal, multiorgan involvement in infancy to isolated, dynamic or static muscle weakness in adulthood.

Patients with glycogen storage diseases affecting the muscles usually complain of random muscle aches and cramps at rest and easy fatigability with exertion and may occasionally have acute rhabdomyolysis induced either by brief, intense isometric exercise or by less intense but sustained dynamic exercise.⁸ Progressive muscle weakness mimicking polymyositis may occur. Serum CK levels may be elevated, EMG and histologic evaluation show myopathy with no inflammation, and even the Peter and Bohan criteria for polymyositis may be fulfilled.⁹ See Table 151.1 for an overview of glycogen storage diseases affecting skeletal muscle.

Myophosphorylase deficiency (McArdle disease, glycogenosis type V)

McArdle disease is an autosomal recessive disease in which phosphorylase, the enzyme catalyzing the removal of 1,4-glucosyl residues from the outer branches of the glycogen molecule, is deficient. It is the most common disorder of skeletal muscle carbohydrate metabolism and one of the most frequent genetic myopathies.²

Onset occurs in the second or third decade with exercise intolerance and muscle cramps. Half of the patients describe episodes of burgundy-colored urine following intense exercise (as a result of rhabdomyolysis). Patients have no difficulty performing moderate exercise at their own pace even for long periods. Crises are induced by brief, intense exercise episodes such as sprinting, as well as by less intense activities such as stair climbing for longer periods. Acute crises are characterized by muscle cramps accompanied by a certain degree of rhabdomyolysis. The pathognomonic sign of McArdle disease is the “second wind” phenomenon, defined as marked improvement in exercise tolerance about 10 minutes into aerobic exercise involving large muscles.¹⁰ During the early phase of moderate exercise, glycogen and anaerobic glycolysis are the main source of energy. After 10 to 15 minutes of moderate to intense exercise, fatty acid metabolism becomes the main energy source, thus leading to a second-wind phenomenon.

Serum CK levels are usually high, even between acute crises. The forearm ischemic test is an excellent screening test and shows a *flat venous lactate curve* with exaggerated elevations in blood ammonia in McArdle disease (Table 151.2). There is a common misconception in the literature regarding the specificity of this test. McArdle disease is, in fact, indistinguishable from phosphofructokinase or debrancher enzyme deficiencies based on results of the forearm ischemic test, and hence diagnostic confirmation is always required. EMG shows myotonic discharges, fibrillations, and positive waves.¹¹ Focal subsarcolemmal and intermyofibrillar accumulations of

Fig. 151.2 Oxidative metabolism of both glucose and free fatty acids depends on converging enzymatic pathways in the cellular mitochondria. The key metabolic intermediate is acetyl coenzyme A (acetyl-CoA), derived both from pyruvate and as an end product of the mitochondrial β -oxidation of fatty acids. Pyruvate is generated from the glycolytic pathway in the sarcoplasm. It diffuses across the mitochondrial membrane and is then converted to acetyl-CoA by pyruvate dehydrogenase. The fatty acids are activated to fatty acyl-CoA derivatives by using adenosine triphosphate (ATP) as the energy source. This activation step occurs within the mitochondrion for short- and medium-chain fatty acids and in the sarcoplasm for long-chain fatty acids. Short- and medium-chain fatty acids enter the mitochondrion by passive diffusion, and long-chain fatty acids enter by facilitated transport via the carnitine shuttle. The carnitine shuttle transports long-chain fatty acids across the outer and inner mitochondrial membranes (OMM and IMM). The long-chain fatty acids are first transferred to carnitine by the enzyme carnitine palmitoyltransferase I (CPT-I), located in the outer membrane space. The fatty acid is then transferred into the mitochondrial matrix by a carnitine acylcarnitine translocase (not shown) located in the IMM. A second enzyme in the IMM, carnitine palmitoyltransferase II (CPT-II), regenerates the fatty acyl-CoA with the release of free carnitine. Within the mitochondrion, the fatty acyl-CoA is oxidized in a four-step cycle of reactions (β -oxidation) in which the β -carbon is oxidized to a ketone followed by cleavage between the α - and β -carbons to yield acetyl-CoA and a fatty acyl-CoA with two fewer carbon atoms. The four enzymes in this cycle include one of three acyl-CoA dehydrogenases (specific for short-, medium-, and long-chain fatty acyl-CoA), an enoyl-CoA hydratase, an oxidized nicotinamide adenine dinucleotide (NAD⁺)-dependent dehydrogenase, and a thiolase. Each cycle of β -oxidation yields 1 mole each of acetyl-CoA, reduced flavin adenine dinucleotide (FADH₂), and reduced NAD (NADH); for a 16-carbon fatty acid such as palmitate the cycle is repeated seven times, which yields 8 moles of acetyl-CoA and 7 moles of FADH₂ and NADH. Acetyl-CoA is oxidized in the tricarboxylic acid (TCA) cycle (Krebs cycle), a series of eight enzymatic reactions. Each mole of acetyl-CoA yields 3 moles of NADH and 1 mole of FADH₂. These reduced nucleotide coenzymes subsequently transfer electrons to molecular oxygen via the electron transport chain and in the process generate ATP from adenosine diphosphate (ADP). The electron transport chain consists of five large protein complexes (I to V) located in the IMM and two small independent components, cytochrome c and ubiquinone. Electrons move sequentially from one protein complex to the next (in the order of I to V) down an energy gradient. In the process, protons are pumped by complexes I, III, and IV across the IMM into the intermembrane space (IMS), thereby creating a membrane potential. GTP, guanosine triphosphate.

normally structured glycogen are seen in muscle biopsy specimens, but histochemical staining for phosphorylase reveals no activity.⁸

No specific treatment is available. Avoiding strenuous exercise is imperative. Glucose intake before exercise may diminish symptoms because the metabolic block is upstream of glucose metabolism.¹² This intervention does not lead to consistent improvement and almost invariably results in weight gain. A high-protein diet and creatine supplementation may increase muscle endurance.^{13,14}

Phosphofructokinase deficiency (glycogen storage disease type VII, Tarui disease)

Tarui disease is an autosomal recessive disease in which the key regulatory enzyme of the glycolytic pathway is deficient. Because of phosphofructokinase deficiency, the muscle is unable to use glucose as an energy source, so glucose intake in these patients leads to an “out-of-wind” phenomenon. The clinical features are similar to those of McArdle disease: muscle aches and cramps induced by exercise, as well as episodes of rhabdomyolysis. The characteristic features of Tarui disease include earlier onset, with the first symptoms occurring in childhood and more severe attacks frequently being associated with systemic symptoms such as nausea and vomiting. A

compensated hemolytic anemia is characteristic and occurs secondary to decreased erythrocyte 2,3-bisphosphoglycerate, which leads to a shortened erythrocyte life span.¹⁵ Serum CK is usually elevated between episodes. The forearm ischemic test shows no lactate elevation. Muscle biopsy demonstrates accumulation of normal glycogen. There is no effective therapy. A high-protein diet and aerobic conditioning have been used in case reports with variable success.¹⁶

Debrancher deficiency (Cori-Forbes disease, glycogenosis type III)

This is yet another autosomal recessive disease characterized by deficiency of the enzyme responsible for removal of the residual stubs of glycogen after digestion by phosphorylase. It is usually classified as a hepatic glycogenosis, but there are two subtypes: type IIIa, in which the enzyme deficiency affects both the liver and muscle, and type IIIb, in which only the liver is involved and debrancher activity in skeletal muscles is normal. The two subtypes can easily be distinguished with the forearm ischemic test, in which abnormal results are produced in type IIIa but not in type IIIb.

In contrast to McArdle and Tarui disease, muscle weakness in type IIIa is minimal in childhood and tends to become severe after the third or fourth

■ **TABLE 151.1**
Glycogen storage diseases affecting skeletal muscles

Type	Defect	Clinical features	Laboratory findings	Treatment
Type II (Pompe disease)	Lysosomal acid maltase	Proximal muscle weakness with pelvic girdle, paraspinal, and diaphragmatic weakness	↑ CK, ↑ AST Decreased or absent acid maltase activity in muscle or cultured skin fibroblasts	Enzyme replacement therapy with αglucosidase alfa, high-protein diet
Type V (McArdle disease)	Myophosphorylase deficiency	Exercise intolerance, muscle cramps, dark red urine after intense exercise Usually occurs in the 2nd or 3rd decade	Myoglobinuria, ↑ CK at rest and after exercise, ↑ NH ₃ and ↑ uric acid with exercise, abnormal enzyme assays in muscles	Ingestion of sucrose, glucose, or fructose immediately before exercise Low-dose creatine supplementation
Type VII (Tarui disease)	Phosphofructokinase	Same as McArdle disease plus severe exercise intolerance, compensated hemolytic anemia, acute exercise intolerance after a carbohydrate load	↑ CK and ↑ bilirubin, reticulocytosis, hyperuricemia Abnormal enzyme assays in muscles	Avoid strenuous exercise for prevention of muscle cramps and myoglobinuria
Phosphoglycerate kinase deficiency	Phosphoglycerate kinase	Same as McArdle disease plus hemolytic anemia and CNS dysfunction	↑ CK (not always), abnormal enzyme assays in muscles	Avoid strenuous exercise for prevention of muscle cramps and myoglobinuria
Lactate dehydrogenase deficiency	Lactate dehydrogenase, M subunit	Same as McArdle disease plus erythematous rash and obstetric difficulties because of uterine stiffness	↑ CK (not always)	Avoid strenuous exercise for prevention of muscle cramps and myoglobinuria
Fructose-1,6-biphosphate aldolase A deficiency	Fructose-1,6-biphosphate aldolase A	Same as McArdle disease plus hemolytic anemia	↑ CK (not always)	Avoid strenuous exercise for prevention of muscle cramps and myoglobinuria
Pyruvate kinase deficiency	Pyruvate kinase	Static symptoms, fixed muscle weakness, cramps	↑ CK (not always)	Avoid strenuous exercise for prevention of muscle cramps and myoglobinuria
Muscle phosphorylase kinase deficiency	Muscle phosphorylase kinase	Same as McArdle disease with muscle atrophy	↑ CK (not always)	Avoid strenuous exercise for prevention of muscle cramps and myoglobinuria

AST, aspartate aminotransferase; CK, creatine kinase; CNS, central nervous system; NH₃, ammonia.

■ **TABLE 151.2**
The forearm ischemic test in metabolic myopathies

	Lactate	Ammonia
Cori disease (GSD type III, liver and muscle involvement)	Impaired response	Normal or enhanced response
Cori disease (GSD type III, liver involvement only)	Normal	Normal
McArdle disease (GSD type V)	Severely impaired response	Normal or enhanced response
Tarui disease (GSD type VII)	Severely impaired response	Normal or enhanced response
Myoadenylate deaminase deficiency	Reduced response	Severely impaired response

GSD, glycogen storage disease.

decade. The weakness is static and additive. Rarely, exercise intolerance may be present.¹⁷ Patients generally have elevated transaminase levels at rest and are at high risk for liver failure, cirrhosis, and hepatocellular carcinoma.¹⁸ The serum CK level is usually elevated. EMG shows myopathy, whereas muscle biopsy specimens show free glycogen accumulation. No effective treatment is available. A high-protein diet is commonly recommended but has not been proved to be of consistent benefit.¹⁴

Acid maltase deficiency (glycogenosis type II, Pompe disease)

In contrast to the other glycogenosis just described, Pompe disease is an autosomal recessive deficiency of the lysosomal enzyme acid maltase that leads to intralysosomal accumulation of glycogen in various tissues.¹⁹ In its infantile form it is universally fatal. In the adult form it may have an onset between the second and sixth decade with progressive, proximal weakness that may mimic polymyositis.²⁰ There is a wide range of phenotypic variability between these two forms. The serum CK level is elevated in all cases. There is no elevation in lactate levels with the forearm ischemic test, and EMG shows evidence of myopathic discharges with occasional myotonic

and complex repetitive discharges.⁸ Muscle biopsy shows periodic acid–Schiff–positive vacuolar myopathy with glycogen storage within lysosomes. Muscle acid maltase activity is decreased to less than 10% of normal. Enzyme replacement with recombinant human α-glucosidase has had some success in treating the infantile form. In adults, benefits have been observed with a high-protein and low-carbohydrate diet.²¹

Fatty acid oxidation disorders

Although these disorders have many overlapping features, three predominant phenotypes can be recognized: hepatic, cardiac, and muscular. A detailed discussion of the first two is beyond the scope of this chapter. The muscle phenotype is characterized by hypotonia and recurrent episodes of rhabdomyolysis. Muscle pain and myoglobinuria are the usual initial signs and are characteristically induced by infection, general anesthesia, or a low-carbohydrate, high-fat diet.²² Patients have no muscle cramps or contractions, and there is no second-wind phenomenon.¹

The major disorders of lipid metabolism that are manifested as isolated myopathy include (1) CPT-II deficiency, (2) very-long-chain acyl-CoA

dehydrogenase (VLCAD) deficiency, and (3) long-chain acyl-CoA dehydrogenase (LCHAD) or trifunctional protein (TFP) deficiency.²³

Carnitine palmitoyltransferase II deficiency

CPT-II deficiency is the most prevalent disorder of lipid metabolism and the most common overall cause of hereditary, recurrent myoglobinuria.²⁴

CPT-II is located in the inner mitochondrial membrane and has the role of transporting long-chain fatty acids from the cytosolic compartment to the mitochondrial matrix so that they can undergo β -oxidation. A wide spectrum of phenotypes is noted in CPT-II deficiency, depending on the severity of the mutation.²⁵ Patients are asymptomatic between episodes. Symptomatic episodes usually develop after prolonged exertion (typically longer than 30 minutes), and patients tolerate brief, intense isometric exercise without difficulty. The typical symptoms and signs of CPT-II deficiency consist of myalgia, cramps, muscle stiffness and tenderness, weakness, and occasionally, myoglobinuria.²⁶ A second-wind or out-of-wind phenomenon is not seen. Similar crises may be induced by stress, fasting, viral infections, fever or exposure to cold, general anesthesia, use of nonsteroidal antiinflammatory drugs, and high doses of diazepam.⁸

A common laboratory finding that is used as a screening test in symptomatic patients is decreased total serum carnitine with an increased acylcarnitine fraction (elevated C16, C18:1, and C18:2). Findings on EMG and the ischemic forearm exercise test are normal. The diagnosis can be confirmed by whole blood DNA analysis, which detects known mutations in approximately 80% of patients.²⁷

The mainstay of treatment is lifestyle changes, which include avoiding prolonged aerobic exercise (longer than 30 minutes), prolonged fasting, and cold exposure, as well as specific dietary requirements, including the use of a high-carbohydrate, low-fat, low-protein diet along with extra carbohydrate intake before sustained exercise.²⁸

Very-long-chain acyl-CoA dehydrogenase deficiency

VLCAD deficiency involves the first step in the fatty acid oxidation of long-chain acyl-CoA intermediates of 20 to 12 carbons in length, thus affecting tissues dependent on fatty acid oxidation for cellular energy production, including the liver, heart, and skeletal muscle. The first symptoms usually occur in the neonatal period and consist of hypoglycemia and irritability. Affected patients have a high risk for recurrent rhabdomyolysis with exercise or other forms of stress, including illness. Dicarboxylic aciduria is universally present. The abnormal acylcarnitine profile is dominated by 5-cis-tetradecenoylcarnitine (C14:1).²⁸ Treatment is based on restriction of long-chain fatty acids in the diet, accompanied by medium-chain triglyceride supplementation.

Long-chain acyl-CoA dehydrogenase deficiency and trifunctional protein deficiency

LCHAD resides in a TFP bound to the inner mitochondrial membrane, along with 2-enoyl-CoA hydratase and 3-ketoacyl-CoA thiolase. Isolated LCHAD deficiency is a common fatty acid oxidation disorder characterized by long-term complications caused by cardiomyopathy, neuropathy, and retinopathy, with a high risk for rhabdomyolysis associated with stress or exercise.²⁹ The diagnosis is made by finding elevated hydroxyl long-chain acylcarnitines (OH-C16, OH-C18:1, and OH-C18:2) in the acylcarnitine profile.²⁸ Enzyme and mutation testing will differentiate isolated LCHAD deficiency from TFP deficiency.

TFP deficiency is more severe, with a high risk for early mortality.²⁹ It seems to be the only fatty acid oxidation disorder in which blood lactate levels are consistently elevated even when the patient is asymptomatic. Clinical features include hypoglycemia, hypotonia, dilated cardiomyopathy in the setting of hydroxydicarboxylic aciduria, and a normal blood acylcarnitine profile.²⁸ Because of their systemic manifestations, LCHAD and TFP deficiencies are unlikely to be confused with the inflammatory myopathies.

Mitochondrial myopathies

This clinically heterogeneous group of disorders results from impairment of oxidative phosphorylation. It has a prevalence of 9.2 per 100,000, which makes it one of the most common inherited neuromuscular disorders.³⁰ Primary mitochondrial myopathies may occur as a result of mitochondrial or nuclear DNA mutations. Those related to mitochondrial DNA mutations are inherited through maternal transmission and become apparent in late childhood or adult life. A smaller number are related to nuclear genes that encode proteins involved in the oxidative phosphorylation pathway, and they are manifested in early childhood. Secondary mitochondrial myopathies are caused by toxins, including zidovudine and clofibrate.

Clinically, they are well-defined syndromes associated with multisystem involvement and are not likely to be confused with the inflammatory myopathies.³¹ Mitochondrial myopathies include Kearns-Sayre syndrome; chronic progressive external ophthalmoplegia (CPEO); mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes (MELAS); Leber hereditary optic neuropathy (LHON); neuropathy, ataxia, retinitis pigmentosa (NARP); myoclonic epilepsy with ragged red fibers (MERFF); mitochondrial neurogastrointestinal encephalomyopathy; and autosomal recessive cardiomyopathy-ophthalmoplegia.

An isolated mitochondrial myopathy may be accompanied by mild proximal limb weakness. Exercise intolerance marked by premature fatigue, headaches, nausea, and vomiting after submaximal exercise may be seen. Symptoms are worsened by fasting, minor illness, and stress.

The mitochondrial metabolic test battery includes CK, lactate and pyruvate, plasma carnitine, blood and urine amino acids, urine organic acids, and cerebrospinal fluid lactate and pyruvate.³² Fasting serum lactate levels are elevated in 70% of patients. The normal lactate-pyruvate ratio (<20:1) is increased. Serum CK is usually normal or mildly elevated. Carnitine levels are decreased with a relative increase in acylcarnitine levels. Muscle biopsy is often required for diagnosis. Histopathologic evaluation reveals characteristic ragged red fibers on Gomori trichrome stain (subsarcolemmal and intermyofibrillar accumulation of mitochondria that appear as bright red masses against the background of blue myofibrils).³² Confirmation of the diagnosis is achieved by molecular genetic testing for mutations most likely thought to be present based on the clinical and laboratory features. Treatment is mainly symptomatic, empirical, and palliative.³³

Myoadenylate deaminase deficiency

AMP deaminase 1 catalyzes the conversion of AMP to inosine monophosphate in skeletal muscle and plays an important role in the purine nucleotide cycle. Deficiency of this enzyme is seen in 2% of muscle biopsy specimens regardless of the indication for biopsy, and it is also found in 2% of healthy, white individuals.³⁴ The clinical manifestation of myoadenylate deaminase deficiency is thus heterogeneous, and it is most commonly asymptomatic. When symptomatic, exercise-induced fatigue, cramps, and myalgia are most common. Occasionally, myoglobinuria and rhabdomyolysis may occur after vigorous exercise. An increased serum creatine kinase level is seen in less than half of affected patients. The forearm ischemic test is highly sensitive and specific for the diagnosis of myoadenylate deficiency. AMP deaminase is the major ammonia-producing enzyme in muscle, so a flat ammonia response accompanied by a rise in plasma lactate is considered sufficient to ensure a reliable diagnosis.³⁵ Findings on EMG are usually normal, with minor abnormalities reported in a small subset of patients. The diagnosis can be confirmed by histochemical stains or enzymatic assays. Myoadenylate deaminase deficiency can subsequently be confirmed in muscle biopsy specimens by histochemical stains or direct enzymatic assay.

DRUG- AND TOXIN-INDUCED MYOPATHIES

A drug-induced myopathy is defined as an acute or subacute occurrence of myopathic symptoms, such as muscle weakness, myalgia, CK elevation, or myoglobinuria, in patients without muscle disease during or after exposure to therapeutic doses of certain drugs. Discontinuation of the offending agent leads to resolution of the symptoms in almost all cases.

The classification of drug- and toxin-induced myopathies according to the type of injury includes the following³⁶:

1. Necrotizing myopathy—the prototype of drug-induced muscle injury. Muscle biopsy specimens are characterized by widespread necrosis with macrophage invasion. Inflammatory infiltrates are not seen. The typical example is statin-induced myopathy.
2. Inflammatory myopathy, which is indistinguishable histologically from polymyositis. It can be caused by statins, interferon alfa, or intramuscular injections of genes.
3. Thick filament loss myopathy. Critical care myopathy is the classic example.
4. Type II muscle fiber atrophy. This is the underlying abnormality in steroid-induced myopathies.
5. Mitochondrial myopathies. Ragged red, cyclooxygenase-negative fibers are seen on histologic examination, as well as increased lipid accumulation. Zidovudine is the typical representative.
6. Lysosomal storage myopathy, which is caused by the accumulation of amphiphilic drugs in lysosomes. Hydroxychloroquine is the classic representative.

7. Antimicrotubule myopathy, which involves disruption of the cytoskeleton. Microtubule inhibition is the main mechanism of action of colchicine.
8. Fasciitis, which is of historical interest because its main representatives include toxic oil syndrome and L-tryptophan. Clinically, these disorders mimic eosinophilic fasciitis.

Statins

Statins are a class of lipid-lowering agents that inhibit hydroxy-3-methylglutaryl-coenzyme A (HMG CoA) reductase (HMGCR). Statin myopathy is defined as muscle aches or muscle weakness in conjunction with increases in creatine phosphokinase (CPK) values to more than 10 times the upper limit of normal. According to the degree of muscle toxicity that they induce, the most myotoxic statin was cerivastatin, which was withdrawn from the market, followed by simvastatin, lovastatin, pravastatin, atorvastatin, and fluvastatin.³⁷

Several clinically relevant scenarios may occur with statin therapy:

1. Asymptomatic elevation of CK up to 10 times the upper normal limit is the most common finding. Based on expert opinion, in this scenario no further changes in treatment are needed as long as the patient remains asymptomatic and the CK elevation remains stable.
2. Myalgia may occur in up to 25% of patients and usually resolves after switching to a different statin or discontinuing therapy.
3. Muscle weakness with CK elevation. Besides the well-described myopathies, an intriguing recent discovery of antibodies against HMGCR in a subset of patients with necrotizing myopathy³⁸ highlighted the statins as the probable culprit of an immune-mediated necrotizing myopathy. If the myopathic symptoms and elevated CK persist with discontinuation of statin therapy, the possibility of an immune-mediated necrotizing myopathy must be considered. Nevertheless, this is a diagnosis of exclusion, and a meticulous workup for autoimmune, metabolic, paraneoplastic, or drug-induced myopathy should be pursued.
4. Rhabdomyolysis is a rare, but serious event characterized by highly elevated CK levels, myoglobinuria, and weakness. It may occur anytime during drug treatment, and the risk may be increased by a number of factors, including age, drug interactions, and renal dysfunction. The most important drug interactions that need to be avoided include the use of statins with amiodarone, cyclosporine, gemfibrozil, macrolides, and azoles.³⁹ Pravastatin is metabolized by a different cytochrome P450 enzyme and seems to be the safest in this group, alongside atorvastatin.

Colchicine

Myopathy, peripheral neuropathy, and rhabdomyolysis have been reported in patients taking colchicine. The myotoxicity of colchicine is thought to be related to disruption of the microtubular cytoskeletal network, which results in intracellular accumulation of autophagic vacuoles. This myopathy may mimic polymyositis and classically occurs in patients taking colchicine for prolonged periods, with proximal muscle weakness and elevated CK developing insidiously. Muscle biopsy specimens are characterized by a vacuolar myopathy without prominent necrosis or inflammation. The myopathy resolves fully 3 to 4 weeks after discontinuing use of the drug. An acute myopathy has also been described in the literature but is very rare. The risk for colchicine myopathy is increased by age, duration of therapy, drug interactions (cyclosporine), and inappropriate dosing in patients with renal insufficiency.

Hydroxychloroquine

Prolonged use of high-dose chloroquine or hydroxychloroquine may lead to a reversible myopathy. Clinically and histologically, this myopathy resembles acid maltase deficiency.³⁶ Progressive weakness and atrophy of proximal muscle groups may occur and be associated with mild sensory changes, tendon reflex depression, and abnormal nerve conduction. Importantly, serum CK levels are normal. Muscle biopsy specimens from patients with chloroquine- or hydroxychloroquine-induced myopathy demonstrate a vacuolar myopathy, often evident only on electron microscopy.⁴⁰ Periodic examination of knee and ankle reflexes should be undertaken and any signs of muscle weakness investigated. Use of hydroxychloroquine should be discontinued if weakness occurs. The myopathy is reversible, but the symptoms may take months to resolve.

Corticosteroids

Exogenous or endogenous glucocorticoid excess leads to weakness secondary to type II fiber atrophy. The mechanism responsible for the steroid effects has not been completely elucidated. Some degree of muscle weakness may eventually develop in the majority of patients treated with corticosteroids, usually after a period of at least 4 weeks. The weakness is more severe and may develop more rapidly in those treated with fluorinated corticosteroids, such as dexamethasone, triamcinolone, and betamethasone, than in those treated with nonfluorinated corticosteroids, such as prednisone and methylprednisolone.⁴¹ The weakness is proximal and accompanied by atrophy of the affected muscles. The distal extremities and oculobulbar and facial muscles are spared. EMG shows low-amplitude motor unit potentials and the absence of any spontaneous electrical activity. Selective atrophy of type II muscle fibers and the absence of inflammation or muscle necrosis are characteristic histologic features.⁴² The recommended treatment of steroid myopathy is reducing the steroid dose or switching to a nonfluorinated steroid and encouraging exercise to prevent disuse atrophy.³²

Toxicity from recreational drugs

Chronic alcoholism may lead to the development of both acute and chronic forms of myopathy. Chronic alcoholic myopathy is characterized by painless, progressive proximal muscle weakness and mild to moderate myopathic changes in muscle biopsy specimens (fiber necrosis, moth-eaten fibers, variability in fiber size, and type II fiber atrophy). Some long-term drinkers may experience an asymptomatic elevation in the serum CK level—as much as 20 times higher than normal levels—that is aggravated by physical activity.³⁶ Acute ethanol myopathy is characterized by severe myalgia, highly elevated CK levels, proximal muscle weakness, and myoglobinuria. Usually, the illness is not severe and patients note resolution of the muscle swelling and pain over a period of 2 weeks. Patients who resume alcohol consumption are particularly prone to subsequent attacks of this form of myopathy.⁴²

ENDOCRINE MYOPATHIES

Thyroid disorders

More than 75% of hypothyroid patients and 67% of hyperthyroid patients have neuromuscular symptoms.⁴³ Neuromuscular manifestations of hypothyroidism include proximal weakness, muscle stiffness and cramping, slow reflexes, and myoedema (local contracture after light percussion). Rarely, hypothyroidism may be accompanied by rhabdomyolysis. Another unusual finding that is sometimes seen in hypothyroid myopathy is muscular enlargement. Hoffman syndrome is defined as the combination of hypothyroidism with muscle stiffness, cramps, and muscular enlargement. Muscle enzymes are commonly high and rarely correlate with the weakness. EMG shows normal findings or mildly myopathic changes. The myopathy resolves with hormone replacement.

In hyperthyroidism, proximal muscular weakness with atrophy, brisk reflexes, and bulbar weakness may occur. Occasionally, distal weakness may be seen as well. Muscle enzymes are normal or low. EMG shows myopathic changes. The symptoms resolve a few months after normalization of thyroid hormone levels.⁴⁴ A rare manifestation of muscular disease in hyperthyroidism is thyrotoxic periodic paralysis. Patients exhibit rapidly progressing paralysis, greater in the lower extremities and often worse in the proximal musculature. The signs and symptoms are clinically identical to those of familial periodic paralysis.

Adrenal disorders

Iatrogenic steroid myopathy is manifested as an insidious, proximal muscular atrophy with weakness. Myalgia may be present. Fluorinated steroid preparations, such as dexamethasone and betamethasone, are most often the culprits. CPK levels are normal and EMG shows no evidence of irritable myopathy. Muscle biopsy specimens typically show evidence of type II fiber atrophy. Cushing disease classically causes proximal weakness and may be severe. Clinically, the myopathy is indistinguishable from iatrogenic steroid myopathies.

Diabetes

Diabetic amyotrophy is a distinctive form of diabetic neuropathy typified by an abrupt onset of pain and asymmetric proximal weakness and wasting of

the legs.⁴⁵ It characteristically affects elderly patients with type 2 diabetes ranging from poor to good control and is often associated with weight loss. EMG shows multifocal denervation in the paraspinal and lower extremity muscles. Nerve conduction studies show an axonal neuropathy. Treatment includes optimizing diabetic control and the use of corticosteroids and intravenous immunoglobulins.

Skeletal muscle infarction is a very rare complication of poorly controlled diabetes mellitus. Patients have an acute onset of painful swelling of the affected muscle and, occasionally, a palpable mass. Because this entity is frequently misdiagnosed clinically, increased clinical awareness is important for early recognition, particularly in a diabetic patient with a painful thigh or leg swelling.⁴⁶

MUSCULAR DYSTROPHIES

Muscular dystrophies are a heterogeneous group of inherited muscular disorders that affect the stability of the sarcolemmal membrane.³²

Duchenne muscular dystrophy

The prototypic example is Duchenne muscular dystrophy, an X-linked recessive disease characterized by the absence of dystrophin. Affected children are normal at birth, only to have a waddling gait, Gower sign (use of the arms to push oneself erect by moving the hands up the thighs), and calf pseudohypertrophy develop by 2 to 6 years of age. Because the stability of the sarcolemmal membrane is affected, there is ongoing degeneration and regeneration leading to elevated CK levels of up to 100 times normal. EMG shows myopathic changes. Muscle biopsy specimens with reduced or absent dystrophin staining are diagnostic. The diagnosis may be confirmed by demonstrating deletion of the dystrophin gene. No specific therapy is available. Death occurs at 14 to 20 years of age as a result of respiratory failure/cardiomyopathy.⁴⁷

Becker muscular dystrophy

Becker muscular dystrophy is very similar to the Duchenne type but has a less severe phenotype because of a partial loss of dystrophin. Patients are typically ambulating until 15 years of age, but otherwise the clinical features are identical, with the exception of muscle biopsy specimens, which may reveal normal dystrophin staining. Dilated cardiomyopathy necessitating heart transplantation may occur.⁴⁷

Emery-Dreifuss muscular dystrophy

Emery-Dreifuss muscular dystrophy is another X-linked recessive disorder that affects emerin. Emerin is an integral protein of the inner nuclear membrane in vertebrates and mediates anchorage of the membrane to the cytoskeleton. Clinically, patients have contractures of the elbows, neck, and spine, as well as scapulohumeroperoneal weakness. Cardiomyopathy and cardiac conduction defects are the most feared complications.⁴⁷

Limb-girdle muscular dystrophies

Limb-girdle muscular dystrophies (LGMDs) are a heterogeneous group of diseases characterized by mutations affecting various structural proteins and enzymes. Their nomenclature is straightforward, with type 1 LGMD being autosomal dominant and type 2 being autosomal recessive. Subclassification with letters denotes specific genetic mutations. They include LGMD2A (calpainopathy; CAPN), LGMD2B (dysferlinopathy; DYSF), LGMD2C (γ -sarcoglycanopathy; SGCG), LGMD2D (α -sarcoglycanopathy; SGCA), LGMD2E (β -sarcoglycanopathy; SGCB), LGMD2F (δ -sarcoglycanopathy; SGCD), LGMD2G (telethoninopathy; TCAP), LGMD2H (TRIM32), LGMD2I (FKRP), LGMD2J (TTN), and LGMD2K (POMT1).⁴⁷ Their prevalence approaches 1 in 100,000. The phenotypes cover the entire range between Duchenne and Becker muscular dystrophies. Patients generally have weakness and wasting restricted to the limb musculature, proximal greater than distal, with initial symptoms occurring in the second or third decade. Muscle biopsy specimens show muscle degeneration and regeneration. Muscle enzymes are typically elevated.⁴²

LGMD2A (calpainopathy) and LGMD2B (dysferlinopathy) are the most common recessive LGMDs in North America. Calpainopathy is frequently associated with profound shoulder-girdle weakness and sometimes scapular winging. Dysferlin deficiency may be accompanied by distal weakness and, in a purely distal form, is associated with severe calf wasting and elevated serum CK levels.⁴⁸ LGMD2B may be misdiagnosed as polymyositis because

of its onset in adult life, marked elevation of serum CK levels, and the presence of inflammatory infiltrates in muscle biopsy specimens.⁴⁹ Confirmation of the diagnosis begins with a muscle biopsy specimen, which demonstrates dystrophic changes, as well as reduced levels or absence of calpain or dysferlin on immunohistochemical staining. Molecular genetic studies are needed to confirm and define the character of the mutation.

The sarcoglycanopathies are forms of LGMD (types 2C, 2D, 2E, and 2F) caused respectively by mutations in the γ -, α -, β -, and δ -sarcoglycan genes, and they affect primarily white individuals. Onset is most often in early childhood, and loss of ambulation generally occurs before the age of 16 years. However, milder phenotypes do occur, with proximal muscle weakness first prompting medical attention in young adulthood. Muscle weakness is initially detectable in the pelvic girdle and later results in scapular winging in the shoulders. Respiratory muscle involvement occurs late in the disease and frequently leads to respiratory failure and death. Serum CK levels are elevated 10 to 100 times the upper limit of normal, typically higher than in the other forms of LGMD.

Myotonic dystrophy

Myotonic dystrophy (Steinert disease, myotonic dystrophy type I, dystrophia myotonica) is the most common adult dystrophy. It is an autosomal dominant disease caused by mutations in the gene that encodes for dystrophia myotonica protein kinase on chromosome 19 (DMPK). The mutation occurs in an untranslated region of the gene. Within the region are 5 to 30 repeating sequences of three nucleotides (CTG trinucleotide repeats). In myotonic dystrophy these CTG repeats expand into the hundreds or thousands. In general, the size of the expansion reflects the severity of the illness.

Clinically, slowly progressive limb weakness, distal more than proximal, is characteristic. The most commonly affected muscles are the facial muscles, distal muscles of the forearm, dorsiflexors of the foot, intrinsic muscles of the hand and feet, and the oropharyngeal and extraocular muscles.⁴⁷ The pelvic girdle, hamstrings, soleus, and gastrocnemius are spared. Myotonia can be elicited by percussing the thenar eminence or by observing delayed muscular relaxation after forceful contractions. CK is normal to mildly elevated and EMG shows myotonic discharges. The extramuscular features have diagnostic and prognostic significance. Smooth and cardiac muscle is most commonly involved, but the central nervous system, bone, and endocrine system may also be affected. Cataracts are almost universal. Testicular atrophy, reduced intelligence, depression, personality disorders, male pattern baldness, diabetes, and sleep apnea are common manifestations.

Proximal myotonic myopathy

Proximal myotonic myopathy (myotonic dystrophy type 2) is milder than myotonic dystrophy. Patients have a slowly progressive proximal myopathy that spares the face. Muscle pain and stiffness may be prominent. Myotonia is not as prominent as myotonic dystrophy on examination. CK is normal to mildly increased, and EMG shows myotonic discharges. Common manifestations include cataracts, cardiac conduction defects, fatigue, and obstructive sleep apnea. Proximal myotonic myopathy may be a close clinical mimic of idiopathic inflammatory myopathies.

INFECTIOUS MYOPATHIES

The musculature is inherently resistant to infections. Infectious myositis is rare and tends to occur in the setting of muscular injury, ischemia, or trauma. Numerous infections can cause myopathy. It is helpful to categorize infectious myositis on the basis of clinical manifestations.⁵⁰

Pyomyositis

Pyomyositis is a primary infection of skeletal muscle that is often associated with abscess formation. Intermuscular abscesses and abscesses extending into muscles by contiguous spread from nearby tissues are not classified as pyomyositis.

Pyomyositis is common in tropical areas and is responsible for up to 4% of hospital admissions in Africa. It is a rare diagnosis in the United States and most commonly described in human immunodeficiency virus (HIV)-infected and immunosuppressed patients, with approximately a third of cases occurring in previously healthy individuals.⁵¹

The most commonly identified etiologic agent is *Staphylococcus aureus* (75% in the United States), followed by group A streptococci, as well as rare cases of groups B, C, and G streptococci, *Pneumococcus*, *Haemophilus*, *Aeromonas*, *Pseudomonas*, *Klebsiella*, and *Escherichia*.

Fig. 151.3 Skeletal muscle uses adenosine triphosphate (ATP) as its fuel for contraction and relaxation. ATP can be generated via four separate metabolic pathways in skeletal muscle. The glycolytic pathway involves the metabolism of glucose derived from blood and the breakdown of muscle glycogen. The anaerobic metabolism of glucose yields pyruvate; in the presence of oxygen, the pyruvate can enter mitochondria and be metabolized further, and in anaerobic conditions, the pyruvate is converted to lactate. Free fatty acids derived from blood enter the mitochondria either as their fatty acyl-coenzyme A (acyl-CoA) derivatives (long-chain fatty acids) or as the intact molecule (short- and medium-chain fatty acids). Within the mitochondria, the fatty acids undergo β -oxidation to generate acetyl-CoA, which is then metabolized by the tricarboxylic acid cycle and the electron donors reduced nicotinamide adenine dinucleotide (NADH) and reduced flavin adenine dinucleotide (FADH₂). Phosphocreatine (PCr) is a high-energy storage compound that provides an immediate source for the regeneration of ATP via the creatine kinase reaction during the initial phases of muscular exertion. Creatine kinase activity is present in the inner mitochondrial membrane and in the sarcoplasm. PCr is regenerated from creatine within the mitochondria via oxidative phosphorylation. The adenylate kinase reaction generates ATP and adenosine monophosphate (AMP) from adenosine diphosphate (ADP). As the concentration of AMP increases during muscle exercise, it is converted to inosine monophosphate (IMP) and ammonia (NH₃) via the myoadenylate kinase reaction.

Most commonly, a single muscle is affected, but in up to 40% of cases, multiple muscles may be involved.⁵² The incidence of pyomyositis by body site may be reviewed in [Figure 151.3](#).

In the initial, invasive stage, local, tender swelling develops with no fluctuation or erythema. Aspiration yields no pus, but 2 or 3 weeks later, the occurrence of high spiking fevers associated with extreme pain and swelling of the affected muscle is the harbinger of the suppurative period. Imaging studies demonstrate an abscess and aspiration yields pus.

Serum CK is usually normal and blood culture results are positive in less than 50% of cases.^{53,54} Besides nonspecific laboratory markers of infection (leukocytosis, C-reactive protein, erythrocyte sedimentation rate, etc.), which are invariably elevated, the most important tool in diagnosis is imaging. Ultrasound is used as the initial screening imaging modality but may show normal findings in the early invasive phase. It may reveal muscle enlargement, or hypoechoic areas consistent with abscesses. Computed tomography may show low-density areas with a surrounding rim of contrast enhancement characteristic of pyomyositis. MRI gives greater anatomic detail and is the *de-facto* imaging “gold standard” for the diagnosis of pyomyositis.

Treatment consists of urgent drainage of any identified abscess, as well as empirical antibiotic coverage with vancomycin in an immunocompetent host or broad-spectrum antibiotic coverage targeting both gram-positive and gram-negative bacteria in immunosuppressed or HIV-infected patients.

Gas gangrene

Gas gangrene is a rapidly progressive life-threatening infection of skeletal muscle caused by clostridia (principally *Clostridium perfringens*). It is due to wound contamination in the setting of severe tissue trauma, inadequate surgical débridement, immunosuppression, and impaired blood supply. Rarely, nontraumatic gas gangrene caused by *Clostridium septicum* may occur in patients with occult gastrointestinal malignancies and lead to transient bacteremia.

Symptoms and signs may evolve over a period of 2 to 3 days, but they may also be fulminant and achieve a peak within 6 hours. Pain out of proportion to the findings on physical examination is followed by the rapid development of septic shock. There is a foul-smelling, serosanguineous,

dirty-appearing discharge with occasional gas bubbles. Crepitus on palpation is the classic hallmark described in the literature, but it may be masked by the massive surrounding tissue edema, and its absence does not rule out gas gangrene. Evidence of air in soft tissues on imaging or high clinical suspicion for gas gangrene is an absolute indication for urgent surgical intervention and débridement of nonviable tissues. Antibiotic therapy with penicillin G and clindamycin is an important adjunct to surgery.

Psoas abscess

A psoas abscess is defined as a purulent infectious collection within the psoas muscle. The psoas muscle is supplied by venous blood from the lumbar spine and has lymphatics from nearby intraabdominal organs overlying it. Secondary psoas abscesses develop as a result of spread of infection from contiguous structures, such as concurrent vertebral infections. Other routes may be from an intraabdominal source, most commonly gastrointestinal, including Crohn disease, cancer, appendicitis, or diverticulitis. Less commonly, psoas abscesses may develop in association with genitourinary infections, such as a perinephric abscess, vaginal delivery, cesarean surgery, abortion, or an infected retroperitoneal hematoma.

Myalgias without eosinophilia

Influenza

Influenza A and B viral myositis occurs most often in children. It is characterized by a sudden onset of calf pain and tenderness, which often results in difficulty walking. The myositis differs from the common initial complaint of myalgia by its later onset, more focal location, and more severe intensity.⁵⁵ CK levels are elevated. If EMG is performed, myopathic changes can be noted. Histopathologic examination of muscle reveals degeneration and necrosis and overall little inflammatory infiltrates. The myositis resolves within a few days with symptomatic treatment.

Human immunodeficiency virus

A slowly progressive myopathy that resembles polymyositis may develop in patients infected with HIV. Patients have myalgia, proximal symmetric

weakness, and elevation of serum CK levels. EMG may show an irritable myopathy indistinguishable from polymyositis.⁵⁶ Muscle biopsy specimens show endomysial, perimysial, or perivascular mononuclear cell infiltrates with muscle fiber necrosis and phagocytosis. Differentiating HIV myopathy from nucleoside reverse transcriptase inhibitor (NRTI) myopathy is a difficult clinical challenge that often requires a trial without NRTIs.

Myalgias with eosinophilia

Among the parasites that cause myositis, *Toxoplasma* is the most common in the United States. Toxoplasmosis can cause an inflammatory myopathy in immunocompromised hosts, often accompanied by fever, encephalitis, and other organ involvement. If isolated, treatment is not generally war-

ranted because the infection is usually self-limited. In severe cases, including progressive myositis, sulfadiazine and pyrimethamine are indicated.

Trichinosis occurs after the ingestion of undercooked pork or wild animal meat. The extraocular muscles are generally involved first, followed by the masseters and muscles of the diaphragm, neck, larynx, and limbs. Rarely, trichinosis can produce a clinical syndrome resembling polymyositis. Eosinophilia is an important diagnostic clue; serologic testing confirms the diagnosis.⁴²

152

Overlap syndromes

■ ROBERT W. HOFFMAN

- Current nomenclature in rheumatology has advanced through the use of autoantibodies as biomarkers.
- Mixed connective tissue disease (MCTD) is widely recognized in children and adults and is characterized by the presence of overlapping clinical features and a high level of antiribonucleoprotein (anti-RNP) antibody.
- The core clinical features of MCTD include Raynaud phenomenon, arthralgia, arthritis, gastroesophageal reflux, and mild myositis.
- The Pm-Scl/PM-1-associated overlap syndrome is characterized by features of polymyositis and scleroderma in the presence of anti-Pm/Scl/PM-1 antibodies.
- Anti-Ku antibody syndrome can have features that overlap with those seen in MCTD, systemic lupus erythematosus (SLE), and Sjögren syndrome.
- Anti-RNA polymerase II antibody syndrome can have features of SLE overlapping with those of limited or diffuse scleroderma.

INTRODUCTION

Correct diagnosis and classification of a disease depend on knowledge of its etiology. The causes of all autoimmune connective tissue diseases are currently unknown, and their diagnosis depends on recognition of patterns of symptoms and signs. Internationally accepted criteria have been developed for the classification of some rheumatic diseases. Even though the use of classification criteria allows reasonably homogeneous patient populations to be selected for epidemiologic studies and clinical trials, it is of more limited value for determining precise treatment regimens in individual patients and for assessing prognosis. The challenges of diagnosis and classification are heightened in rheumatology in general and the autoimmune connective tissue diseases in particular by the tendency for one disease to merge with another. This results in an overlapping spectrum of clinical features among the rheumatic diseases, including the classically recognized entities such as systemic lupus erythematosus (SLE), systemic sclerosis, and polymyositis/dermatomyositis. Identification and characterization of specific antinuclear antibodies (ANAs) as biomarkers of disease have greatly assisted in the classification and diagnosis of systemic rheumatic diseases.

CLASSIFICATION AND DIAGNOSIS OF OVERLAP SYNDROMES

Nomenclature, taxonomy, disease classification, and diagnosis

The current classification scheme of disease can be dated back to Victorian England and pioneering work of the British epidemiologist William Farr, who is considered by many to be the founder of medical statistics. This system of disease classification, which is also known as disease taxonomy or disease nomenclature, is based on a hierarchic structure that uses consensus criteria. For a more complete discussion of this topic, see Chapter 1.

Classification criteria are essential for epidemiologic studies and clinical trials; they help ensure that the participants included both within a single study and across multiple studies are similar. The current system of disease classification is built on an anatomic focus of disease. This approach to classification, founded by William Farr, includes recognition of symptomatologic and epidemiologic patterns of disease. However, the focus on anatomic and symptomatologic patterns of disease rather than mechanisms of disease may not take full advantage of recent advances in science.

A focus on molecular mechanisms of disease, particularly when recent advances in immunology, imaging, and genetics are incorporated, has the potential to substantially advance disease classification. In rheumatology, all three of these modalities have been applied successfully to disease classification and diagnosis. For example, radiographic imaging is used for the classification of rheumatoid arthritis (RA) and ankylosing spondylitis. HLA-B27 genotyping combined with magnetic resonance imaging is used for the classification of ankylosing spondylitis. Measurements of rheumatoid factor and anti-citrullinated peptide antibodies (ACPAs) are criteria for the classification of RA; ANAs, anti-double-stranded DNA (dsDNA), and anti-Sm are criteria for the classification of SLE (see Chapters 91 and 130).

An important advance in the classification of rheumatic diseases has been the use of serologic immunologic testing for identification of autoantibodies and inclusion of these autoantibodies in the classification of many rheumatic diseases, including autoantibodies against ANA, dsDNA, Smith (Sm), U1-ribonucleoprotein (RNP), SSA (Ro), SSB (La), phospholipids, ACPA, and rheumatoid factor. These and other autoantibodies illustrate the value of immunologic testing and applying an understanding of disease pathogenesis to disease classification and diagnosis (see Chapters 91 and 130).

Finally, it is important to recognize the proper use and the limitations of classification criteria, as well as their distinction from diagnostic criteria. Classification criteria are designed for application in epidemiologic studies and clinical trials, and they are limited by current knowledge of disease. For example, unrecognized subsets of disease or multiple diseases may be included within a current classification scheme, which limits the validity of the criteria. Classification criteria differ from diagnostic criteria, and the two should not generally be used interchangeably. Diagnosis of any individual patient should incorporate knowledge of the disease as applied to the patient's specific circumstance. Disease at initial evaluation will often not encompass the full spectrum of clinical manifestations, which require time to develop fully. For many rheumatic diseases, including the entities reviewed in this chapter, validated and widely accepted diagnostic criteria are yet to be published.

Terms defined

Undifferentiated connective tissue disease

The term "undifferentiated connective tissue disease" (UCTD) was first applied by LeRoy and colleagues¹ to describe the early and often "undifferentiated" phase of a rheumatic disease at initial evaluation when a precise classification could not be made because the patient did not fulfill the recognized classification criteria. "UCTD" as applied by LeRoy and colleagues was not intended to describe a patient with an "overlap" syndrome who has features of two or more distinctly recognizable rheumatic diseases but rather one who lacks sufficient features to meet the criteria for any classification.¹ As LeRoy and associates described, many patients will have subsequent involvement of additional organs over time, and this often assists in correct disease classification. At a later time the patient may meet the classification criteria for a rheumatic disease.

TABLE 152.1
Autoantibodies as biomarkers for disease classification and diagnosis

Autoantibody specificity	Disease
U1-RNP	Mixed connective tissue disease
tRNA synthetase	Myositis with arthritis and pulmonary involvement
PM/Scl (PM-1)	Overlapping features of polymyositis and limited scleroderma
Ku	Polymyositis and systemic sclerosis
RNA polymerase II	Overlap with systemic lupus erythematosus
SSA (Ro)	Primary and secondary Sjögren syndrome

In the literature the term UCTD has also been used to describe a group of patients who despite careful observation over time will continue to fail to meet the classification criteria for any well-recognized rheumatic disease.² Notably, some authors have required that such UCTD patients have a positive fluorescent ANA test result. Recognition of these multiple uses of the term UCTD can assist in reading this sometimes confusing literature.

Overlap syndrome

A term that warrants definition is “overlap syndrome.” This term has been used to convey a variety of meanings by different authors. Frequently, the term has been used to describe patients exhibiting the features of more than one distinct clinical entity. Some have used the term to describe the predominance of selected clinical features, such as interstitial lung involvement or myopathy (i.e., myositis-pulmonary overlap), in patients with another widely recognizable rheumatic disease such as SLE or RA. The term is used here to describe the latter.

In the absence of pathognomonic clinical features or diagnostic laboratory test results, the correct diagnosis or classification of any patient may be challenging. The rheumatic diseases exhibit substantial overlapping clinical and immunologic features, which often makes classification difficult. Historic examples of diseases with overlapping signs and symptoms that are now considered distinct entities, including rheumatic fever, Lyme disease, calcium pyrophosphate deposition disease, RA, and ankylosing spondylitis, illustrate these challenges. As our understanding of the etiopathogenesis of the rheumatic diseases advances, there will certainly be increasing clarity in the classification and ease of diagnosis of apparent overlapping rheumatic entities. The focus of this chapter is on systemic autoimmune diseases with overlapping features of widely recognized multisystemic autoimmune diseases, including SLE, RA, scleroderma, polymyositis/dermatomyositis, and Sjögren syndrome.

Autoantibodies as a biomarker for classification

As early as the 1950s important advances were made in the use of serologic markers of disease, including the identification and characterization of autoantibodies, which can serve as markers for diagnosis and classification of the rheumatic diseases. This work began with the identification of rheumatoid factor and ANAs. Further identification and characterization of autoantibodies in the 1970s to 1980s, including the use of specific newly identified autoantibodies for classification, ultimately led to the recognition and classification of antiphospholipid (aPL) syndrome, mixed connective tissue disease (MCTD), and overlap syndromes with predominant muscle and lung involvement as distinctly identifiable entities. A summary of these conditions is presented in Table 152.1. The topic of aPL syndrome is reviewed elsewhere in this text (see Chapter 139); a comprehensive description of MCTD and overlap diseases characterized by the presence of specific autoantibodies accompanied by lung and muscle involvement is presented in this chapter.

MIXED CONNECTIVE TISSUE DISEASE

Introduction

MCTD was first described by Gordon C. Sharp and colleagues.³ It was characterized by overlapping features of SLE, scleroderma, and polymyositis in the presence of a newly identified antibody found at very high levels in

SCHEMATIC REPRESENTATION OF THE U1-RNP MOLECULE

Fig. 152.1 Polypeptides bound to U1-RNA. The polypeptides illustrated in purple (70-kDa and A) contain the epitopes that are predominantly recognized by anti-U1-RNP antibodies, and those shown in yellow contain the epitopes that are predominantly recognized by anti-Sm antibodies (B/B' and D). Also shown here is the other U1-associated C polypeptide that forms the U1-specific complex with 70-kDa and A, as well as the Sm polypeptides B/B', D, E, F, and G, which bind to U1, U2, U3, and U4/6 RNA (which are not shown).

TABLE 152.2
Clinical features of mixed connective tissue disease

Clinical feature	At diagnosis (%)	Cumulative findings (%)
Raynaud phenomenon	89	96
Arthralgia/arthritis	85	96
Swollen hands	60	66
Esophageal dysmotility	47	66
Pulmonary disease	43	66
Sclerodactyly	34	49
Pleuritis/pericarditis	34	43
Rash	30	53
Myositis	28	51
Renal disease	2	11
Neurologic disease	0	17

Data from Burdett MA, Hoffman RW, Deutscher SL, et al. Long-term outcome in mixed connective tissue disease: longitudinal clinical and serologic findings. *Arthritis Rheum* 1999;42:899-909.

patients' sera. This autoantibody, first called extractable nuclear antigen, is now known as anti-RNP. It has been demonstrated to be a nuclear RNP and is also known to be noncovalently associated with U1-RNA; in addition, it is known as U1-RNP (Fig. 152.1).^{4,5} All three terms are used interchangeably in the literature to describe this autoantibody.

History

Since the original description of MCTD by Sharp and colleagues more than 4 decades ago, the disease has become widely recognized around the world in both adults and children.³⁻¹³ The most common clinical features are listed in Table 152.2 and include Raynaud phenomenon, arthralgia, arthritis, and gastroesophageal reflux. Laboratory features include the presence of high levels of anti-RNP antibody, high-titer speckled-pattern fluorescent ANAs, leukopenia, hypergammaglobulinemia, and anemia. An example of diffuse hand swelling with typical sausage-shaped fingers in a patient with MCTD is illustrated in Figure 152.2.

Classification and diagnosis

Even though no diagnostic criteria have been widely accepted yet, at least four classification criteria have been proposed for MCTD. Among these

Fig. 152.2 Sausage-shaped fingers in a patient with mixed connective tissue disease, which is seen most often in the early edematous phase of the disease.

BOX 152.1 CRITERIA FOR MIXED CONNECTIVE TISSUE DISEASE

Serologic criteria

Anti-ribonucleoprotein antibody must be present at a moderate to high level in serum
AND

Clinical criteria

At least 3 of the following 5 clinical findings must be present:

- Edema of the hand
- Synovitis
- Myositis
- Raynaud phenomenon
- Acrosclerosis

AND these clinical criteria must include either synovitis or myositis

From Alarcon-Segovia D, Cardiel MH. Comparison between 3 diagnostic criteria for mixed connective tissue disease. Study of 593 patients. *J Rheumatol* 1989;16:328-34.

criteria, those of Alarcon-Segovia and Cardiel are perceived to be the easiest to apply.¹⁴ A slightly modified form of the MCTD classification of Alarcon-Segovia and Cardiel is presented in [Box 152.1](#).

Clinical features

The clinical features of MCTD seen most frequently at initial evaluation and a summary of the cumulative clinical features observed over time from the longitudinal study of Burdt and colleagues⁷ that included follow-up for as long as 20 years are presented in [Table 152.2](#). Many studies from around the world in both adults and children have reported features of MCTD similar to those reported by Burdt and colleagues.⁷⁻¹³

Initially, the most common manifestations are Raynaud phenomenon, arthralgia, arthritis, diffusely swollen hands, and esophageal reflux.⁷ Other uncommon findings have also been described, including trigeminal neuropathy, seizure, psychosis, and pulmonary hypertension.

Diagnosis requires the presence of a high level of anti-RNP antibodies in serum, and other laboratory features often include leukopenia, lymphopenia, and mild anemia (see later for a detailed discussion of immunologic and laboratory testing in MCTD). Pleuritis, pericarditis, rash, and myositis may also develop over time in the typical patient as additional features of MCTD, in addition to the manifestations widely seen at initial evaluation (see [Table 152.2](#)). Among the most serious complications of MCTD is pulmonary involvement, including pulmonary hypertension, which is the most common disease-related cause of death.⁷

Skin

The most common skin manifestations of MCTD are Raynaud phenomenon and diffusely swollen hands (see [Fig. 152.2](#)), which may evolve into sclerodactyly ([Fig. 152.3](#)). Other rashes occur in approximately half of all patients and include photosensitivity rash, malar rash, and telangiectases over the face. Oral ulcers similar to those found in lupus may occur, and rashes

Fig. 152.3 Hands of a patient with mixed connective tissue disease showing features of both dermatomyositis (thickening and erythema of the dorsum of the fingers) and scleroderma (sclerodactyly and fixed flexion of the fingers).

typical of dermatomyositis, including Gottron papules or a heliotrope rash, have commonly been observed in MCTD.

Hands and joints

Arthralgia ultimately occurred in more than 90% of patients in the study of Burdt and associates,⁷ and inflammatory arthritis developed in approximately half of all patients. Rheumatoid factor is found in 25% to 50% of patients; however, erosions are uncommon. A Jaccoud-like arthritis, similar to that seen in SLE, has been described in MCTD.

Muscles

Myalgia occurs in 25% to 50% of patients, and myositis has been reported to be widely variable and variously reported in 25% to 75% of patients. The most common muscle-related findings appear to be muscle discomfort with elevated creatinine kinase levels in the absence of significant muscle weakness. This is typically an early feature of MCTD. Fibromyalgia has also been reported to occur in MCTD.

Pulmonary

Pulmonary hypertension is one of the most serious complications that can occur in MCTD. In the longitudinal study of Burdt and colleagues,⁷ pulmonary hypertension was the most common disease-related cause of death in patients with MCTD. It accounted for death in 13% during the follow-up period. In addition, interstitial lung disease can develop, with fibrosis occurring in approximately half of these patients. Pleural inflammation similar to that seen in SLE can also occur. Rare cases of pulmonary hemorrhage have been described.

Gastrointestinal

Symptomatic esophageal reflux is very common in patients with MCTD. Symptoms include heartburn, dysphagia, and less commonly, odynophagia and regurgitation of food. Other regions of the bowel, including the colon and small intestines, can be involved. In addition to esophageal dysmotility with reflux, the next most common gastrointestinal features of MCTD are bacterial overgrowth syndromes and malabsorption. Gastrointestinal involvement similar to that seen in scleroderma can occur.

Sicca

A study by Setty and coworkers¹⁵ found that secondary Sjögren syndrome occurs in approximately 25% of all patients with MCTD and is frequently accompanied by the presence of anti-SSA (Ro) antibodies. The presence of anti-SSA (Ro) antibodies was further correlated with photosensitivity and malar rash. Patients may have salivary or submandibular gland enlargement similar to that seen with primary Sjögren syndrome.

Cardiac

Cardiac involvement as detected by echocardiography or electrocardiography occurs in approximately a quarter of all patients with MCTD. Pericardial involvement is common and similar to that seen with lupus. Right heart involvement associated with pulmonary hypertension is among the most serious cardiac complication in MCTD.⁷ Less common manifestations that have been reported include various types of valvular abnormalities, septal hypertrophy, and myocarditis. Atherosclerotic heart disease, which is among

■ **TABLE 152.3**
Management of mixed connective tissue disease

Clinical feature	Treatment (mild vs. moderate to severe disease)
Arthralgia/arthritis	Mild—antimalarial, NSAIDs Moderate to severe—systemic corticosteroids, methotrexate, azathioprine while avoiding tumor necrosis factor–blocking agents because of potential risk for disease flare
Raynaud phenomenon	Mild—protective measures Moderate—calcium channel blockers may be of benefit Severe—scleroderma-like management
Rash	Mild—protective measures to avoid the sun, antimalarial, and topical corticosteroids Moderate to severe—systemic corticosteroids, immunosuppressant, including azathioprine
Esophageal reflux	Mild—avoidance measures Moderate to severe—proton pump inhibitor, endoscopy with screening for Barrett esophagus; dilatation rarely
Myositis	Mild—antimalarial, corticosteroids Moderate to severe—corticosteroids, methotrexate, and IVIG, similar to the management of polymyositis
Pulmonary involvement	Yearly screening with pulmonary function testing and pulmonary imaging may be beneficial for the identification of early disease or as clinically indicated*† Moderate to severe—cyclophosphamide immunosuppression or treatment as for primary pulmonary hypertension may be beneficial (see the references cited*†)
Cardiovascular	Modify risk factors Yearly screening with ECG and echocardiography may be beneficial for the identification of early disease or as clinically indicated
Sicca	Symptomatic treatment
Sexual dysfunction	Treat erectile dysfunction as indicated and identify and treat androgen deficiency in men; treat vaginal dryness; counsel
Pregnancy and contraception	Monitor as for a high-risk pregnancy; SSA (Ro) and RNP have been associated with congenital heart block in neonates; pregnancy outcomes reported to be favorable from experienced centers Counsel on risk for sexually transmitted diseases, contraceptive options, risk and potential teratogenicity of medications; avoid estrogen-containing contraceptives
General	Antimalarial unless contraindicated; appropriate vaccines for age and risk; modify cardiovascular risk; promote healthy lifestyle, including exercise, diet, and risk avoidance; monitor and treat depression when present; suicidality may be a risk

ECG, electrocardiography; IVIG, intravenous immunoglobulin; NSAID, nonsteroidal antiinflammatory drug; RNP, ribonucleoprotein.

T cells.¹⁹ Innate immune signaling through Toll-like receptors 7 and 3 appear to be involved.

Management

Currently, no treatment of MCTD has been approved by the U.S. Food and Drug Administration or the European Medical Agency. Therefore, all treatments recommended are for off-label use of medication and are based on best practices and expert opinion.^{20,21} A summary of the management of MCTD is presented in Table 152.3.

Pm-Scl (PM-1)-ASSOCIATED OVERLAP SYNDROME

Patients with antibodies against the Pm-Scl antigen have features of both polymyositis and scleroderma, including sclerodactyly, proximal scleroderma, Raynaud phenomenon, and pulmonary involvement.²²⁻²⁴ These patients generally do not progress to widespread or diffuse sclerodermatous involvement of the skin, but renal involvement similar to what can occur in scleroderma with hypertensive crisis has been reported.

RARE OVERLAP SYNDROMES: Ku AND RNA POLYMERASE

The initial report of patients with anti-Ku antibodies described them to have features of polymyositis and scleroderma; Ku is an 80-kDa DNA binding protein. Subsequent reports documented that Ku antibody–positive patients may have a wide range of clinical signs and symptoms, including features seen in MCTD, SLE, and Sjögren syndrome.²⁵

Patients with SLE and both limited and diffuse scleroderma have been reported to have antibodies reactive with RNA polymerase I and III. Patients

with selective reactivity against RNA polymerase II antibodies have been reported who exhibit an SLE overlap syndrome. Patients with selective RNA polymerase II reactivity have also been reported to have reactivity with Ku, RNP, and topoisomerase I.²⁶

CONCLUSION

Although diagnosis and classification of all the rheumatic diseases ultimately will be determined by increased understanding of their etiology, the fact remains that currently the causes of all autoimmune connective tissue diseases are unknown and their diagnosis depends on recognition of patterns of symptoms and signs. The challenges of diagnosis and classification are heightened in the autoimmune connective tissue diseases by the overlapping spectrum of clinical features among these diseases. Identification and characterization of specific ANAs as biomarkers of disease have, however, greatly assisted in classification and diagnosis of these systemic rheumatic diseases. MCTD is now widely recognized in adults and children as a distinct disease entity by physicians around the world. The use of autoantibodies as biomarkers for the diagnosis and classification of MCTD, SLE, and RA is widely accepted. Specific autoantibodies can also be useful for the diagnosis of tRNA synthetase–, Pm-Scl/PM-1–, Ku–, and RNA polymerase–associated overlap syndromes.

Acknowledgments

Dr. Patrick J. W. Venables is gratefully acknowledged for his contribution to previous editions of this chapter, which have been drawn on in writing the current edition. Dr. Gordon C. Sharp is also acknowledged for his many seminal contributions to the field of rheumatology, including his original description of mixed connective tissue disease and his characterization of important autoantibodies that have become universally used for classification of the rheumatic diseases.

THE VASCULITIDES

153

Classification and epidemiology of vasculitis

■ PETER A. MERKEL ■ ALFRED D. MAHR

- The vasculitides are a heterogeneous group of diseases linked by common clinical, laboratory, and pathophysiologic features.
- Classification and diagnostic criteria have substantial implications for clinical practice and clinical research in vasculitis.
- The American College of Rheumatology Criteria for the Classification of Vasculitis and the definitions of the Chapel Hill Consensus Conference on the Nomenclature of Systemic Vasculitides are widely used for clinical research in vasculitis.
- Epidemiologic studies have helped advance hypotheses regarding the causes of many vasculitides.
- Both genetic and environmental factors have been shown to play roles in the pathogenesis of vasculitis.

INTRODUCTION

The term *vasculitis* refers to several diseases involving inflammation of blood vessels with subsequent tissue destruction and/or organ failure. The systemic vasculitides can be considered as a group of disorders because they have in common inflammatory vascular disease as the primary or a substantive pathologic process and also have overlapping clinical features.

All types of primary or idiopathic vasculitis are considered rare diseases, reaching “orphan” status in the United States (i.e., they affect fewer than 200,000 persons). However, the prevalence of different forms of vasculitis varies greatly both geographically and ethnically, which raises intriguing questions about specific genetic and environmental influences on the pathogenesis.

Diagnostic and classification criteria have substantial implications for clinical practice as well as for clinical and epidemiologic research. This chapter reviews and discusses the implications of these concepts for our understanding of vasculitis.

Classification, definitions, and diagnostic criteria for vasculitis

A number of systems have been proposed for the classification and diagnosis of the vasculitides. It is recognized that such systems are imperfect, and the classification and diagnosis of vasculitis is an ever-evolving process. Nonetheless, these systems are used in most of the clinical research, are applied to treatment guidelines, and are used in daily communication among clinicians.

History and evolution of vasculitis classification systems

The first classification system for the vasculitides was proposed by the pathologist Pearl Zeek in 1952 and included only five entities. Although this system clearly omitted many diseases now recognized as vasculitis, it was a major advance in the field, and all subsequent attempts at classification have essentially evolved from her original format.

Many other vasculitis classification schema have been proposed.¹ Most are modifications of prior systems incorporating newly described separate entities (e.g., Kawasaki disease), removing entities no longer considered to be vasculitis (e.g., lymphomatoid granulomatosis), or adapting the terminology to reflect better understanding of pathophysiology and new diagnostic tests (e.g., antineutrophil cytoplasmic antibodies, or ANCA). The central organizing themes of these classification systems vary from predominant vessel size, to associated diseases, to putative pathophysiology/causality, to clinical manifestations, or, most commonly, to some amalgamation of all these factors.

Antineutrophil cytoplasmic antibody-associated vasculitis

The term ANCA-associated vasculitis is now widely used to cover granulomatosis with polyangiitis (formerly known as *Wegener granulomatosis*), microscopic polyangiitis, and eosinophilic granulomatosis with polyangiitis (formerly known as *Churg-Strauss vasculitis*). However, this term may cause confusion since patients may have these diagnoses even if tests for ANCA are negative. Nonetheless, “ANCA-associated vasculitis” has become an accepted subclassification for vasculitis, as formalized in the 2012 revision of the Chapel Hill nomenclature.²

Table 153.1 provides an outline of the major forms of vasculitis with reference to the factors listed earlier.

CONCEPT OF DEFINITIONS, CLASSIFICATION SYSTEMS, AND DIAGNOSTIC CRITERIA FOR VASCULITIS

It is important to distinguish the terms *disease classification*, *disease definitions*, and *diagnostic criteria*, because they are obviously related but provide unique contributions to the field.

Classification systems for vasculitis aim to differentiate among patients correctly known to have a form of vasculitis to create homogeneous subsets for clinical research. Classification criteria can be inappropriately used for diagnosis.

Definitions for vasculitis aim to provide a standard name that is linked to the fundamental pathologic features inherent in the given disease and aim for inclusion of pathognomonic findings. Such definitions of diseases need to be widely accepted and applied within a field of study.

TABLE 153.1
The systemic vasculitides

	Predominant vessel size			ANCA-associated	Granuloma
	Large	Medium	Small		
Primary vasculitides					
Giant cell arteritis	Yes				Yes
Takayasu arteritis	Yes				Yes
Isolated aortitis					Yes
Polyarteritis nodosa		Yes			
Kawasaki disease		Yes			
Granulomatosis with polyangiitis (Wegener granulomatosis)		Possible	Yes	Yes	Yes
Microscopic polyangiitis		Possible	Yes	Yes	
Eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome)		Possible	Yes	Yes	Yes
Immunoglobulin A vasculitis (Henoch-Schönlein purpura)			Yes		
Cryoglobulinemic vasculitis			Yes		
Behçet disease	Yes	Yes	Yes		
Anti-glomerular basement membrane disease (Goodpasture syndrome)			Yes		
Buerger disease		Yes	Yes		
Cogan syndrome	Yes	Yes	Yes		
Relapsing polychondritis	Yes	Yes	Yes		
Urticarial vasculitis		Yes	Yes		
Primary angiitis of the central nervous system		Yes	Yes		Yes

Other connective tissue diseases			Yes		
Infection	Yes	Yes	Yes		
Drugs		Yes	Yes	Possible	
Malignancies	Yes	Yes	Yes		

ANCA, antineutrophil cytoplasmic antibody.

Data from Mahr AD, Merkel PA. Vasculitis. In: Creager M, editor. Atlas of vascular medicine. 3rd ed. Philadelphia: Current Medicine Group/Springer; 2007.

Diagnostic criteria for vasculitis aim to allow clinicians to determine if a specific disease is present; they are usually more detailed than classification criteria and include both general and specific data elements. Diagnostic criteria are crucial for practicing clinicians to help them direct diagnostic evaluations and thus provide proper care.

The 1990 American College of Rheumatology vasculitis classification system

By far the most widely used classification system is the 1990 American College of Rheumatology (ACR) Criteria for the Classification of Vasculitis (Table 153.2, Table e153.1).³ The stated purpose of these criteria is to provide guidance for clinical research studies of a selected set of seven types of vasculitis.

Strengths of the ACR classification system include the imprimatur of the ACR, the data-driven approach, and its simplicity of use since the criteria are based mostly on clinically relevant and commonly obtained information items. The wide adoption of this system is evidence both that it is useful and that it addressed an unmet need in the field.

The ACR classification criteria for vasculitis also have some important limitations:

1. The criteria include only seven diseases, and alternative systems are needed to study other types of primary vasculitis and all secondary forms.
2. The criteria were produced without a gold standard for any of the diagnoses under study; this limitation would be common to any classification system.
3. There was no attempt to group or link diseases in any manner, a positive feature of other classification systems.

There are also limitations common to any such system that is now 20 years old, including that the criteria do not incorporate newer diagnostic tests, especially testing for ANCA, and that specific forms of vasculitis have subsequently been suggested either for adoption for use in clinical practice (microscopic polyangiitis) or for elimination from use (hypersensitivity vasculitis). Similarly, patients with vasculitis may fulfill more than one set of ACR criteria. To address some of these issues, a hierarchic algorithm was proposed to supplement the ACR criteria and Chapel Hill definitions (see later) that includes additional histologic and laboratory data (Fig. e153.1).⁴ Similarly, positive results on ANCA testing was an added item in the “modified” ACR criteria for granulomatosis with polyangiitis used in some recent clinical studies.⁵

Nonetheless, the ACR classification criteria are the most commonly applied criteria in the field, and any attempt to revisit the classification of the vasculitides will be compared with the ACR system.

Classification of childhood vasculitides

The Pediatric Rheumatology European Society (PReS) and the European League Against Rheumatism (EULAR) formed a group to develop separate classification criteria for five types of childhood vasculitides, including Kawasaki disease (not included in the ACR criteria).⁶ The resulting criteria include, but are not restricted to, data elements found in both the ACR classification and the Chapel Hill definitions (see later). The resulting overall classification system is outlined in Box e153.1 and the detailed criteria for the five specific forms of vasculitis are presented in Box e153.2.

Although it is important to ensure that those vasculitides that are either unique to childhood or more common during childhood are recognized by classification and nomenclature systems, creating a full set of separate criteria for vasculitis in childhood creates a new set of challenges. Most

■ TABLE e153.1

American College of Rheumatology 1990 classification criteria for vasculitis

Disease	Criteria	Definition
Giant cell (temporal) arteritis ¹⁴⁰ (need 3 of 5 criteria for classification)	Age at disease onset ≥50 yr New headache Temporal artery abnormality Elevated erythrocyte sedimentation rate Abnormal temporal artery biopsy	Development of symptoms or findings beginning at age 50 or older New onset of or new type of localized pain in the head Temporal artery tenderness to palpation or decreased pulsation, unrelated to arteriosclerosis of cervical arteries Erythrocyte sedimentation rate ≥ 50 mm/hr by Westergren method Biopsy specimen with artery showing vasculitis characterized by a predominance of mononuclear cell infiltration or granulomatous inflammation, usually with multinucleated giant cells
Takayasu arteritis ¹⁴¹ (need 3 of 6 criteria for classification)	Age at disease onset ≤40 yr Claudication of extremities Decreased brachial artery pulse Blood pressure (BP) difference > 10 mm Hg (between arms) Bruit over subclavian arteries or aorta Arteriogram abnormality	Development of symptoms or findings related to Takayasu arteritis at age ≤40 yr Development and worsening of fatigue and discomfort in muscles of one or more extremity while in use, especially the upper extremities Decreased pulsation of one or both brachial arteries Difference of >10 mm Hg in systolic blood pressure between arms Bruit audible on auscultation over one or both subclavian arteries or abdominal aorta Arteriographic narrowing or occlusion of the entire aorta, its primary branches, or large arteries in the proximal upper or lower extremities, not due to arteriosclerosis, fibromuscular dysplasia, or similar causes; changes usually focal or segmental
Polyarteritis nodosa ¹⁴² (need 3 of 10 criteria for classification)	Weight loss ≥4 kg Livedo reticularis Testicular pain or tenderness Myalgias, weakness, or leg tenderness Mononeuropathy or polyneuropathy Diastolic BP > 90 mm Hg Elevated blood urea nitrogen (BUN) or creatinine Hepatitis B virus Arteriographic abnormality Biopsy of small or medium-sized artery containing polymorphonuclear neutrophils	Loss of ≥4 kg body weight since illness began, not due to dieting or other factors Mottled reticular pattern over the skin of portions of the extremities or torso Pain or tenderness of the testicles, not due to infection, trauma, or other causes Diffuse myalgias (excluding shoulder and hip girdle) or weakness of muscles or tenderness of leg muscles Development of mononeuropathy, multiple mononeuropathies, or polyneuropathy Development of hypertension with the diastolic BP > 90 mm Hg Elevation of BUN > 40 mg/dL or creatinine > 1.5 mg/dL, not due to dehydration or obstruction Presence of hepatitis B surface antigen or antibody in serum Arteriogram showing aneurysms or occlusions of the visceral arteries, not due to arteriosclerosis, fibromuscular dysplasia, or noninflammatory causes Histologic changes showing the presence of granulocytes and mononuclear leukocytes in the artery wall
Wegener granulomatosis ¹⁴³ (granulomatosis with polyangiitis) (need 2 of 4 criteria for classification)	Nasal or oral inflammation Abnormal chest radiograph Urinary sediment Granulomatous inflammation on biopsy	Development of painful or painless oral ulcers or purulent or bloody nasal discharge Chest radiograph showing the presence of nodules, fixed infiltrates, or cavities Microhematuria (>5 red blood cells per high-power field) or red cell casts in urine sediment Histologic changes showing granulomatous inflammation within the wall of an artery or in the perivascular or extravascular area (artery or arteriole)
Churg-Strauss syndrome ¹⁴⁴ (allergic granulomatosis and angiitis, eosinophilic granulomatosis with polyangiitis) (need 4 of 6 criteria for classification)	Asthma Eosinophilia Mononeuropathy or polyneuropathy Pulmonary infiltrates, nonfixed Paranasal sinus abnormality Extravascular eosinophils	History of wheezing or diffuse high-pitched rales on expiration Eosinophilia > 10% on the white blood cell differential Development of mononeuropathy, multiple mononeuropathies, or polyneuropathy (i.e., glove/stocking distribution), attributable to systemic vasculitis Migratory or transitory pulmonary infiltrates on radiographs (not including fixed infiltrates), attributable to systemic vasculitis History of acute or chronic paranasal sinus pain or tenderness or radiographic opacification of the paranasal sinuses Biopsy including artery, arteriole, or venule, showing accumulation of eosinophils in extravascular areas
Henoch-Schönlein purpura (immunoglobulin A vasculitis) ¹⁴⁵ (need 2 of 4 criteria for classification)	Palpable purpura Age ≤20 yr at disease onset Bowel angina Wall granulocytes on biopsy	Slightly raised "palpable" hemorrhagic skin lesions, not related to thrombocytopenia Patient ≤20 yr at onset of first symptoms Diffuse abdominal pain, worse after meals, or the diagnosis of bowel ischemia, usually including bloody diarrhea Histologic changes showing granulocytes in the walls of arterioles or venules
Hypersensitivity vasculitis ¹⁴⁶ (need 3 of 5 criteria for classification)	Age at disease onset ≥16 yr Medication at disease onset Palpable purpura Maculopapular rash Biopsy including arteriole and venule	Development of symptoms after age 16 Medication was taken at the onset of symptoms that may have been a precipitating factor Slightly elevated purpuric rash over one or more areas of the skin; does not blanch with pressure and is not related to thrombocytopenia Flat and raised lesions of various sizes over one or more areas of the skin Histologic changes showing granulocytes in a perivascular or extravascular location

BOX e153.2 EULAR/PreS CLASSIFICATION CRITERIA OF CHILDHOOD VASCULITIDES**Classification criteria for immunoglobulin A vasculitis (Henoch-Schönlein)**

Palpable purpura (mandatory criterion) in the presence of at least one of the following four features:

- Diffuse abdominal pain
- Any biopsy showing predominant immunoglobulin A deposition
- Arthritis* or arthralgia
- Renal involvement (any hematuria and/or proteinuria)

Classification criteria for Kawasaki disease

Fever persisting for at least 5 days (mandatory criterion) plus four of the following five features:

- Changes in peripheral extremities or perineal area
- Polymorphous exanthema
- Bilateral conjunctival injection
- Changes of lips and oral cavity: injection of oral and pharyngeal mucosa
- Cervical lymphadenopathy

In the presence of coronary artery involvement (detected on echocardiography) and fever, fewer than four of the remaining five criteria are sufficient (the exact number of criteria required is to be defined in the validation phase).

Classification criteria for childhood polyarteritis nodosa

A systemic illness characterized by the presence of either a biopsy showing small and mid-size artery necrotizing vasculitis OR angiographic abnormalities[†] (aneurysms or occlusions) (mandatory criteria), plus at least two of the following:

- Skin involvement (livedo reticularis, tender subcutaneous nodules, other vasculitic lesions)
- Myalgia or muscle tenderness
- Systemic hypertension, relative to childhood normative data
- Mononeuropathy or polyneuropathy
- Abnormal urine analysis and/or impaired renal function[‡]
- Testicular pain or tenderness
- Signs or symptoms suggesting vasculitis of any other major organ system (gastrointestinal, cardiac, pulmonary, or central nervous system)

Classification criteria for granulomatosis with polyangiitis (Wegener)

Three of the following six features should be present:

- Abnormal urinalysis[§]
- Granulomatous inflammation on biopsy[¶]
- Nasal sinus inflammation
- Subglottic, tracheal, or endobronchial stenosis
- Abnormal chest x-ray or CT
- PR3 ANCA or C-ANCA staining

Classification criteria for Takayasu arteritis

Angiographic abnormalities (conventional, CT, or MR) of the aorta or its main branches (mandatory criterion), plus at least one of the following four features:

- Decreased peripheral artery pulse(s) and/or claudication of extremities
- Blood pressure difference >10 mm Hg between arms
- Bruits over aorta and/or its major branches
- Hypertension (related to childhood normative data)

*Acute, any joint.

[†]Should include conventional angiography if magnetic resonance angiography is negative.

[‡]Glomerular filtration rate of <50% normal for age.

[§]Hematuria and/or significant proteinuria.

[¶]If a kidney biopsy is done, it characteristically shows necrotizing pauci-immune glomerulonephritis.

ANCA, antineutrophil cytoplasmic antibodies; CT, computed tomography; EULAR, European League Against Rheumatism; MR, magnetic resonance; PR3, proteinase 3; PreS, Pediatric Rheumatology European Society.

Adapted from Ozen S, Ruperto N, Dillon MJ, et al. EULAR/PreS endorsed consensus criteria for the classification of childhood vasculitides. *Ann Rheum Dis* 2006;65:936-41.

TABLE 153.2
American College of Rheumatology 1990 classification criteria for vasculitis

Disease	Criteria
Giant cell (temporal) arteritis (need 3 of 5 criteria for classification)	Age at disease onset ≥ 50 yr New headache Temporal artery abnormality Elevated erythrocyte sedimentation rate Abnormal temporal artery biopsy
Takayasu arteritis (need 3 of 6 criteria for classification)	Age at disease onset ≤ 40 yr Claudication of extremities Decreased brachial artery pulse Blood pressure (BP) difference > 10 mm Hg between arms Bruit over subclavian arteries or aorta Arteriogram abnormality
Polyarteritis nodosa (need 3 of 10 criteria for classification)	Weight loss ≥ 4 kg Livedo reticularis Testicular pain or tenderness Myalgias, weakness, or leg tenderness Mononeuropathy or polyneuropathy Diastolic BP > 90 mm Hg Elevated blood urea nitrogen or creatinine Hepatitis B virus Arteriographic abnormality Biopsy of small or medium-sized artery containing polymorphonuclear neutrophils
Wegener granulomatosis (granulomatosis with polyangiitis) (need 2 of 4 criteria for classification)	Nasal or oral inflammation Abnormal chest radiograph Urinary sediment Granulomatous inflammation on biopsy
Churg-Strauss syndrome (allergic granulomatosis and angiitis; eosinophilic granulomatosis with polyangiitis) (need 4 of 6 criteria for classification)	Asthma Eosinophilia Mononeuropathy or polyneuropathy Pulmonary infiltrates, nonfixed Paranasal sinus abnormality Extravascular eosinophils
Henoch-Schönlein purpura (immunoglobulin A vasculitis) (need 2 of 4 criteria for classification)	Palpable purpura Age ≤ 20 yr at disease onset Bowel angina Wall granulocytes on biopsy
Hypersensitivity vasculitis (need 3 of 5 criteria for classification)	Age at disease onset ≥ 16 yr Medication at disease onset Palpable purpura Maculopapular rash Biopsy including arteriole and venule

Data from Hunder GG, Arend WP, Bloch DA, et al. The American College of Rheumatology 1990 criteria for the classification of vasculitis. *Introduction. Arthritis Rheum* 1990;33:1065-7.

importantly, there is the potential for different classification or diagnostic systems for the same diseases in children and adults; this could lead to confusion clinically and problems with including or comparing data from clinical trials across age groups. The field should work toward development and adoption of comprehensive sets of classification and diagnostic criteria applicable to the range of vasculitides seen in both childhood and adulthood.

Other classification criteria for vasculitides

Many other systems have been developed or proposed to classify or diagnose single vasculitides. The International Study Group for Behçet's Disease "diagnostic" criteria⁷ (Table e153.2) and the Japanese Behçet's Disease Research Committee criteria^{8,9} for Behçet disease, the American Heart Association¹⁰ "diagnostic" criteria for Kawasaki disease (Box e153.3), and classification criteria for mixed cryoglobulinemic vasculitis¹¹ each refer to vasculitides that were not included in the ACR Classification Criteria.

Additionally, other systems are used either to complement or to replace the ACR classification criteria, including the Lanham criteria for eosinophilic granulomatosis with polyangiitis,¹² the "diagnostic" criteria for Takayasu arteritis of Ishikawa¹³ (subsequently revised by Sharma and

colleagues¹⁴), the criteria for the "diagnosis" of immunoglobulin A (IgA) vasculitis (Henoch-Schönlein purpura),^{15,16} and "diagnostic" criteria for polyarteritis nodosa.¹⁷

The Chapel Hill Consensus Conference definitions

In 1994 an international group of medical experts in vasculitis from various medical disciplines met as the Chapel Hill Consensus Conference on the Nomenclature of Systemic Vasculitis (CHCC) and published their conclusions and proposals.¹⁸ The goals of the conference were, through a modified nominal group process, to agree upon the names of several forms of vasculitis and "construct root definitions for the vasculitides so named." The group stated that they were specifically *not* aiming to create a new classification scheme or diagnostic criteria for vasculitis; the CHCC definitions are meant to complement existing classification systems. In 2012 an expanded set of experts, including several members of the original 1994 group, revised the nomenclature to include new insights gained over the two intervening decades, added more forms of vasculitis and addressed issues surrounding eponyms.

The CHCC process has established a set of names and definitions for 10 forms of vasculitis (Table 153.3). Although these definitions emphasize specific pathologic findings, it was recognized that histologic criteria may be appropriately replaced by surrogate indicators. For example, although "granulomatous inflammation of the aorta and its major branches" is the definition of Takayasu arteritis, angiographic abnormalities may be assumed to indicate such aortitis.

Important advances of the CHCC proposals include the incorporation of the testing of ANCA and the inclusion of the name *microscopic polyangiitis*, which helped solidify the use of this term to define a disease now considered separate from polyarteritis nodosa. The 2012 revision extended the number and scope of vasculitides addressed by the nomenclature and should help standardize how vasculitis is referred to in the medical literature.

The CHCC proposal also has some weaknesses. The definitions were derived from consensus of expert opinion without formal validation and reliability testing and still rely on some partially subjective data elements since even histologic findings are not fully objective. For example, pathologists may view the same set of slides from a lung biopsy specimen but differ as to whether "granulomatous inflammation" is present.

The CHCC approach has had unintended consequences in that these definitions are regularly, and many feel, inappropriately applied in clinical research studies as both classification and diagnostic criteria. For example, the application of either the CHCC definitions or ACR criteria to patients with clinical diagnoses of polyarteritis nodosa or ANCA-associated vasculitides has been shown to result in substantial discordances in categorization.¹⁹

Changes regarding the use of eponyms to name vasculitides

The use of eponyms to name diseases occurs in vasculitis perhaps more so than in any other group of rheumatic diseases and has led to problems and controversies. *Wegener granulomatosis* has recently been replaced with *granulomatosis with polyangiitis* due to Dr. Wegener's association with the Nazi regime.²⁰ In keeping with the movement to replace honorific eponyms with more scientifically descriptive names, the 2012 CHCC nomenclature proposed new names for some other vasculitides (see Table 153.3).

Diagnostic criteria for vasculitis

Despite 50 years of increasingly intense study of vasculitis and multiple attempts at creating systems to describe these diseases, a generally accepted cohesive and complete set of diagnostic criteria has never been established for the vasculitides.

Neither the ACR criteria nor the CHCC definitions are ideal for use in establishing a diagnosis of vasculitis.

When formally tested for use as diagnostic criteria, the ACR classification criteria did not perform well.²¹ Similarly, the CHCC definitions were found to have poor sensitivity for the diagnosis of granulomatosis with polyangiitis (Wegener granulomatosis) and microscopic polyangiitis.²²

Current status of classification, nomenclature, and diagnostic criteria for vasculitis

Classification criteria, disease definitions, and diagnostic criteria for the vasculitides have been in a state of continued evolution for more than 50 years, and the current systems, despite the shortcomings outlined earlier,

■ **TABLE e153.2**
International Study Group diagnostic criteria for Behçet disease

<i>Recurrent oral ulceration</i>	Minor aphthous, major aphthous, or herpetiform ulceration observed by physician or patient, which recurred at least 3 times in one 12-mo period
Plus two of:	
<i>Eye lesions</i>	Anterior uveitis, posterior uveitis, or cells in vitreous on slit-lamp examination or Retinal vasculitis observed by ophthalmologist
<i>Skin lesions</i>	Erythema nodosum observed by physician or patient, pseudofolliculitis, or papulopustular lesions or Acneiform nodules observed by physician in postadolescent patients not receiving corticosteroid treatment
<i>Positive pathergy test</i>	Read by physician at 24-48 hr

*Findings applicable only in the absence of other clinical explanations.

BOX e153.3 AMERICAN HEART ASSOCIATION DIAGNOSTIC CRITERIA FOR KAWASAKI DISEASE

- Fever of at least 5 days' duration
- Presence of four of the following principal features:
 - Changes in extremities
 - Polymorphous exanthem
 - Bilateral conjunctival injection
 - Changes in the lips and oral cavity
 - Cervical lymphadenopathy
- Exclusion of other diseases with similar findings*

*Include measles, scarlet fever, drug reactions, Stevens-Johnson syndrome, other febrile viral exanthemas, Rocky Mountain spotted fever, Staphylococcal scalded skin syndrome, toxic shock syndrome, juvenile rheumatoid arthritis, leptospirosis, mercury poisoning. Patients with fever and fewer than four principal clinical features can be diagnosed as having Kawasaki disease when coronary artery disease is detected by two-dimensional echocardiography or coronary angiography.

■ TABLE 153.3

Names and definitions of vasculitides adopted by the Chapel Hill Consensus Conference (CHCC) on the nomenclature of systemic vasculitis

CHCC 2012 name	CHCC 2012 definition
Large vessel vasculitis (LVV)	Vasculitis affecting large arteries more often than other vasculitides. Large arteries are the aorta and its major branches. Any size artery may be affected.
Takayasu arteritis (TAK)	Arteritis, often granulomatous, predominantly affecting the aorta and its major branches. Onset usually in patients younger than 50 yr.
Giant cell arteritis (GCA)	Arteritis, often granulomatous, usually affecting the aorta and/or its major branches, with a predilection for the branches of the carotid and vertebral arteries. Often involves the temporal artery. Onset usually in patients older than 50 yr and often associated with polymyalgia rheumatica.
Medium vessel vasculitis (MVV)	Vasculitis predominantly affecting medium arteries defined as the main visceral arteries and their branches. Any size artery may be affected. Inflammatory aneurysms and stenoses are common.
Polyarteritis nodosa (PAN)	Necrotizing arteritis of medium or small arteries without glomerulonephritis or vasculitis in arterioles, capillaries, or venules, and not associated with antineutrophil cytoplasmic antibodies (ANCA).
Kawasaki disease (KD)	Arteritis associated with the mucocutaneous lymph node syndrome and predominantly affecting medium and small arteries. Coronary arteries are often involved. Aorta and large arteries may be involved. Usually occurs in infants and young children.
Small vessel vasculitis (SVV)	Vasculitis predominantly affecting small vessels, defined as small intraparenchymal arteries, arterioles, capillaries, and venules. Medium arteries and veins may be affected.
ANCA-associated vasculitis (AAV)	Necrotizing vasculitis, with few or no immune deposits, predominantly affecting small vessels (i.e., capillaries, venules, arterioles, and small arteries). Associated with myeloperoxidase (MPO) ANCA or proteinase 3 (PR3) ANCA. Not all patients have ANCA. Add a prefix indicating ANCA reactivity, e.g., MPO-ANCA, PR3-ANCA, ANCA-negative.
Microscopic polyangiitis (MPA)	Necrotizing vasculitis, with few or no immune deposits, predominantly affecting small vessels (i.e., capillaries, venules, or arterioles). Necrotizing glomerulonephritis is very common. Pulmonary capillaritis often occurs. Granulomatous inflammation is absent.
Granulomatosis with polyangiitis (Wegener) (GPA)	Necrotizing granulomatous inflammation usually involving the upper and lower respiratory tract, and necrotizing vasculitis affecting predominantly small to medium vessels (e.g., capillaries, venules, arterioles, arteries, and veins). Necrotizing glomerulonephritis is common.
Eosinophilic granulomatosis with polyangiitis (Churg-Strauss) (EGPA)	Eosinophil-rich and necrotizing granulomatous inflammation often involving the respiratory tract, and necrotizing vasculitis predominantly affecting small to medium vessels, and associated with asthma and eosinophilia. ANCA is more frequent when glomerulonephritis is present.
Immune complex vasculitis	Vasculitis with moderate to marked vessel wall deposits of immunoglobulin and/or complement components predominantly affecting small vessels (i.e., capillaries, venules, arterioles, and small arteries). Glomerulonephritis is frequent.
Anti-glomerular basement membrane (anti-GBM) disease	Vasculitis affecting glomerular capillaries, pulmonary capillaries, or both, with GBM deposition of anti-GBM autoantibodies. Lung involvement causes pulmonary hemorrhage, and renal involvement causes glomerulonephritis with necrosis and crescents.
Cryoglobulinemic vasculitis (CV)	Vasculitis with cryoglobulin immune deposits, affecting small vessels (predominantly capillaries, venules, or arterioles) and associated with serum cryoglobulins. Skin, glomeruli, and peripheral nerves are often involved.
Immunoglobulin A vasculitis (Henoch-Schönlein) (IgAV)	Vasculitis, with IgA1-dominant immune deposits, affecting small vessels (predominantly capillaries, venules, or arterioles). Often involves skin and gastrointestinal tract, and frequently causes arthritis. Glomerulonephritis indistinguishable from IgA nephropathy may occur.
Hypocomplementemic urticarial vasculitis (HUV) (anti-C1q vasculitis)	Vasculitis accompanied by urticaria and hypocomplementemia affecting small vessels (i.e., capillaries, venules, or arterioles), and associated with anti-C1q antibodies. Glomerulonephritis, arthritis, obstructive pulmonary disease, and ocular inflammation are common.
Variable vessel vasculitis (VVV)	Vasculitis with no predominant type of vessel involved that can affect vessels of any size (small, medium, and large) and type (arteries, veins, and capillaries).
Behçet's disease (BD)	Vasculitis occurring in patients with Behçet's disease that can affect arteries or veins. Behçet's disease is characterized by recurrent oral and/or genital aphthous ulcers accompanied by cutaneous, ocular, articular, gastrointestinal, and/or central nervous system inflammatory lesions. Small vessel vasculitis, thromboangiitis, thrombosis, arteritis, and arterial aneurysms may occur.
Cogan syndrome (CS)	Vasculitis occurring in patients with Cogan syndrome characterized by ocular inflammatory lesions, including interstitial keratitis, uveitis, and episcleritis, and inner ear disease, including sensorineural hearing loss and vestibular dysfunction. Vasculitic manifestations may include arteritis (affecting small, medium, or large arteries), aortitis, aortic aneurysms, and aortic and mitral valvulitis.
Single-organ vasculitis (SOV)	Vasculitis in arteries or veins of any size in a single organ that has no features that indicate that it is a limited expression of a system vasculitis. The involved organ and vessel type should be included in the name (e.g., cutaneous small vessel vasculitis, testicular arteritis, central nervous system vasculitis). Vasculitis distribution may be unifocal or multifocal (diffuse) within an organ. Some patients originally diagnosed as having SOV will develop additional disease manifestations that warrant redefining the case as one of the systemic vasculitides (e.g., cutaneous arteritis later becoming systemic polyarteritis nodosa).
Vasculitis associated with systemic disease	Vasculitis that is associated with and may be secondary to (caused by) a systemic disease. The name (diagnosis) should have a prefix term specifying the systemic disease (e.g., rheumatoid vasculitis, lupus vasculitis).
Vasculitis associated with probable etiology	Vasculitis that is associated with a probably specific etiology. The name (diagnosis) should have a prefix term specifying the association (e.g., hydralazine-associated microscopic polyangiitis, hepatitis B virus-associated vasculitis, hepatitis B virus-associated cryoglobulinemic vasculitis).

From Jennette JC, Falk RJ, Bacon PA, et al. 2012 Revised International Chapel Hill Consensus Conference nomenclature of vasculitides. *Arthritis Rheum* 2013;65:1-11.

have proved quite useful for clinicians and clinical researchers. However, there is still room for progress. The existence and use of multiple such systems leads to confusion, and the resulting heterogeneity may hamper clinical research and comparison of clinical studies in vasculitis.

There is a need to continue to work toward a set of classification and diagnostic criteria that are inclusive, are comprehensive, are meaningful to both researchers and clinicians, include both children and adult patients, incorporate readily available and reliable clinical data, are derived more through a data-driven process than expert opinion, reflect current understanding of the pathophysiology of the various diseases, and achieve international acceptance. Furthermore, the classification and diagnostic systems should ideally share common data elements and avoid contradictions. The international vasculitis community is currently conducting a large collaborative project aimed at readdressing both classification and diagnostic criteria for the vasculitides.

EPIDEMIOLOGY OF VASCULITIS

The principles of epidemiology are described in Chapter 1. Both descriptive and analytic epidemiologic research techniques have been applied to the study of vasculitis.

Epidemiologic research in vasculitis

Several intriguing clinical observations have stimulated epidemiologic research in vasculitis. Observations of racial, geographic, periodic, or seasonal variations in disease frequency for some vasculitides raise fascinating issues and generate hypotheses about the underlying causes of these diseases. However, epidemiologic research also faces several challenges. Because all vasculitides are rare diseases and substantial resources are required to collect data for larger numbers of patients, the quality of the epidemiologic data accumulated for the vasculitides is heterogeneous. Although some disorders have been well studied, for others epidemiologic characteristics remain poorly understood. Furthermore, differences in diagnostic classification, as discussed in the previous section, are also an important concern.

The following section summarizes the knowledge on epidemiology for the most common vasculitides. Some primary vasculitides (e.g., central nervous system vasculitis or anti-glomerular basement membrane disease) and the secondary vasculitides are not covered.

Vasculitides predominantly affecting large vessels *Giant cell arteritis*

Giant cell arteritis (GCA) is the most common among the primary vasculitides with an annual incidence (in the population of individuals at least 50 years of age) between 2.4 and 32.8 cases per 100,000 people.²³⁻⁴⁰ [Table e153.3](#) summarizes the available incidence data for GCA. Studies strongly suggest that GCA affects primarily populations of Northern European ancestry and rarely occurs outside of white populations.⁴¹ There is evidence that the incidence of GCA has increased over the last 50 years by a factor of 2 to 5,⁴² a trend at least partly explained by an increased awareness of the disease by clinicians and identification of patients with negative findings on temporal artery biopsy.^{42,43}

The role of genetic factors is indirectly suggested by observations of familial cases of GCA⁴⁴ and by occurrence of GCA in monozygotic twins.⁴⁵ There is also a well-established association between GCA and the HLA class II genes and particularly the HLA-DRB1*04 allele, which is carried by more than 50% of patients according to case series.^{25,40,46-51} Various other genetic polymorphisms have been described in the context of GCA; for example, the genes encoding tumor necrosis factor, ICAM-1, RANTES, MICA, interleukin-1 (IL-1) receptor antagonist,⁵² and IL-10.⁵³

An infectious cause of GCA has been suggested by periodic and seasonal variations in its incidence, as well as by the observation that the initial development of GCA is often preceded by infectious episodes^{24,26,32,39,54}; however, neither sets of initial findings have been able to be reproduced.^{28,39,55} Furthermore, studies seeking to identify a causal infectious agent for GCA have yielded mixed results.^{34,56-61}

Other environmental factors associated with GCA include smoking,^{62,63} hormonal factors (as suggested by the negative association between number of pregnancies and GCA),⁶⁴ a history of previous atherosclerotic vascular disease,^{62,63} and sun exposure.⁵⁴

Takayasu arteritis

Epidemiologic data on Takayasu arteritis are scarce. The clinical observation that Takayasu arteritis might predominantly affect nonwhite

populations—for example, Asians or South Americans—is not yet well substantiated by the scarce descriptive population-based studies. The annual incidence of Takayasu arteritis has been estimated in different geographic regions quite uniformly with rates (per million inhabitants) of 0.4 in Denmark,⁶⁵ 0/4 to 0.8 in the United Kingdom,⁶⁶ 0.8 in Sweden,⁶⁷ 1 to 2 in Japan,⁶⁸ 2.2 in Kuwait,⁶⁹ and 2.6 in the United States.⁷⁰ In contrast, prevalence estimates suggest that Takayasu arteritis might indeed be several-fold more common in Japan (40 per million inhabitants)⁶⁶ compared with the United Kingdom (4.7 to 7.1)⁶⁶ or Sweden (6.4).⁶⁷

A genetic predisposition to Takayasu arteritis is suggested by findings of an association between Takayasu arteritis and HLA alleles, particularly HLA-B52^{71,72} and HLA-B39.⁷¹ A genomewide association study identified further susceptibility loci within the HLA region and within the *FCGR2A/FCGR3A* locus.⁷³ The long-suggested hypothesis that infection with *Mycobacterium tuberculosis* might play a role in the pathogenesis of Takayasu arteritis⁷⁴ remains unconfirmed.

Vasculitides predominantly affecting medium-sized vessels *Polyarteritis nodosa*

Epidemiologic data referring to polyarteritis nodosa (PAN) must be interpreted cautiously in light of the wide variability that exists in the diagnostic and classification criteria for PAN. The prevalence and annual incidence of PAN were estimated, respectively, at 2 to 33 per million inhabitants⁷⁵⁻⁷⁹ and 0 to 16 per million inhabitants.⁸⁰⁻⁸⁵

There is circumstantial evidence that PAN is associated with chronic hepatitis B virus infection,⁸⁵⁻⁸⁷ and this association is now well accepted. Data from case series suggest that in the 1970s and 1980s, approximately half of the patients diagnosed with PAN were chronically infected with the hepatitis B virus.⁸⁸ Over the past 20 years, the percentage of patients with PAN associated with hepatitis B virus in Western nations has become much smaller, likely as a consequence of large vaccination campaigns against hepatitis B virus.⁸⁸ It is commonly believed that PAN affects white people almost exclusively.⁷⁷

Kawasaki disease

Kawasaki disease (KD) is the most common form of vasculitis in children. The annual incidence (per 100,000 children younger than 5 years of age) is estimated at 216 in Japan⁸⁹ and at 113 in Taiwan.⁹⁰ To date, more than 180,000 cases have been recorded in Japan,⁹¹ with three notable peaks in incidence occurring in 1979, 1982, and 1986. Seasonal variation in the onset of KD has been described, with outbreaks occurring in the winter and the spring.⁹²

Outside of Asia, KD is much less common, with an approximately 10-fold to 20-fold lower incidence than that reported by studies in Asia.⁴¹ In addition, in the United States, KD affects children of Asian descent much more than African American or white children.⁹³

Genetic studies using candidate gene approaches have not been able to convincingly demonstrate a genetic predisposition to KD, and KD does not seem to be associated with any specific HLA antigen. One study suggested a possible role for genes involved in the synthesis of immunoglobulins.⁹⁴ Much stronger evidence for a genetic underpinning to KD was provided by recent genomewide association studies, which identified *FCGR2A* and several other loci as putative contributors to KD susceptibility.⁹⁵⁻⁹⁸

Several factors point strongly toward an infectious cause of KD, including the onset in early childhood, the clinical manifestations, the existence of secular peaks in the incidence, and seasonal variations. An association between KD and a history of a previous respiratory infection has been demonstrated⁹⁹; however, no specific microorganism has yet been linked to KD. Other associations with KD reported include exposure to rug shampoo¹⁰⁰ and residence in a home near water.⁹³

Vasculitides predominantly affecting small vessels *Granulomatosis with polyangiitis*

Among the three ANCA-associated vasculitides, granulomatosis with polyangiitis (GPA) is the best studied with respect to epidemiology. Prevalence and annual incidence rates of GPA, which have been reported mostly for Europe, were estimated at 24 to 160 per million inhabitants and 2.1 to 15 per million inhabitants, respectively¹⁰¹ ([Fig. 153.1](#) and [Table e153.4](#)). These data suggest a rise in the frequency of GPA over the last several decades, which can be at least partially explained by the introduction and widespread availability of ANCA testing since the late 1980s.¹⁰¹

The results of descriptive studies support a decreasing north-to-south gradient in the incidence of GPA in the Northern Hemisphere¹⁰² (see

EGPA, eosinophilic granulomatosis with polyangiitis; GPA, granulomatosis with polyangiitis; MPA, microscopic polyangiitis.

Fig. 153.1 Prevalence of systemic vasculitides per 1,000,000 persons (for GPA, MPA, and EGPA) or per 100,000 persons (for Behçet disease) in various countries. Values represent ranges from several studies with some averaging/rounding performed. Map is not perfectly to scale.

Fig. 153.1). The increased frequency in higher latitudes could point to a protective role of sunlight exposure.¹⁰³ Evidence is also increasing with respect to the low risk of GPA in Asian or African populations.^{77,104} A comparative analysis of populations in the United Kingdom and Japan found similar incidence rates for ANCA-associated vasculitis, but GPA was seven times less commonly seen in the Japanese population.¹⁰⁴

The knowledge of the role of genetics in the development of GPA has increased substantially in recent years. The most widely reproduced genetic link to GPA identified by case-control studies using a candidate gene approach relates to the Z allele of the gene encoding α_1 -antitrypsin (*SERPINA1*).¹⁰⁵ Associations of GPA with HLA antigens and other genes, including those encoding PTPN22, proteinase 3, and CTLA-4, have been reported by candidate gene studies.¹⁰¹ Some of these association were recently replicated by two genomewide association studies, which yielded associations of GPA with the HLA-DPB region,^{106,107} *SERPINA1*, and the gene encoding proteinase 3.¹⁰⁶

Compared with the effect of genetic factors, the role of environmental factors in causing GPA remains relatively poorly investigated. Exposure to silica is the most consistently reported risk factor and confers a risk increase (odds ratio) of between 2 and 14.¹⁰¹ The results of case-control studies suggested other environmental risk factors; for example, farming and exposure to livestock, organic solvents, industrial pollutants, or pesticides.¹⁰¹ The hypothesis of an infectious origin of GPA has been long emphasized, but no causal microorganism has yet been identified. Nasal carriage of *Staphylococcus aureus* has been linked to an increased risk of disease relapses.¹⁰⁸ Studies focusing on seasonal variations in the onset of GPA have yielded conflicting results.¹⁰⁹

Microscopic polyangiitis

The epidemiology of microscopic polyangiitis (MPA) is less well described than that of GPA (see Fig. 153.1 and Table e153.4). Based on reported estimates, the prevalence of MPA varies from 0 to 94 per million inhabitants and the annual incidence varies from 1 to 10.1 per million inhabitants in Europe.¹⁰¹ In Kuwait and Japan, the annual incidence of MPA has been estimated to be 24.5 and 18.2 per million inhabitants, respectively.^{101,104} Comparisons of incidence rates have raised the possibility that MPA is more common in Asian than in European populations¹⁰⁴ and has a frequency gradient inverse to the one seen in GPA, with a greater frequency in the countries in the south of Europe¹⁰² (see Fig. 153.1). However, the existence of such a gradient remains to be confirmed and is called into question by recent Swedish studies that reported high prevalence and incidence figures for MPA.¹⁰¹

Only a few genetic studies have specifically focused on MPA. Most studies examined MPA together with GPA or within a combined set of ANCA-positive vasculitides with antimyeloperoxidase specificity. MPA has been associated with a polymorphism of a gene coding for IL-10.¹¹⁰ In Japan, a link has been shown between MPA and the HLA-DRB*0901 allele,^{111,112} the I-haplotype DRB1*0901-DQB1*0303,¹¹³ and killer cell immunoglobulin-like receptor genotypes.¹¹³ A link has also been shown between the number of copies of the FCGR3B gene and the risks of MPA or GPA in European patients.¹¹⁴ More recently, a genomewide association study in Europe found that MPA was associated with HLA-DQ.¹⁰⁶

As is true for GPA, silica exposure was shown to be a risk factor for MPA.¹⁰¹

Eosinophilic granulomatosis with polyangiitis

Eosinophilic granulomatosis with polyangiitis (EGPA) is the least common of the ANCA-associated vasculitides. The few descriptive investigations carried out in Europe and Australia indicate that EGPA prevalence ranges between 2 and 22 per million inhabitants¹⁰¹ (see Fig. 153.1 and Table e153.4). The annual incidence (per million inhabitants) has been estimated at 0 to 3.7 in Europe, 2.2 to 2.3 in Australia, 0.8 to 2.8 in New Zealand,¹⁰¹ and 2.4 in Japan.¹⁰⁴

Genetic candidate gene association studies suggest that HLA-DRB1*04 and DRB1*07 are potential susceptibility factors for EGPA.^{115,116} Another study found an association of the functional variant of IL-10 gene in ANCA-negative cases of EGPA.¹¹⁷

Because EGPA usually occurs in association with asthma and allergy symptoms, including rhinitis and sinusitis, a hypersensitivity response has been proposed for the pathogenesis of EGPA. Many observations were reported of the occurrence of EGPA following exposure to various medications, vaccination, or desensitization,¹¹⁸ but none of these studies was definitive or accounted for the majority of cases. Much attention has focused on the potential causal or triggering role of leukotriene receptor antagonists (e.g., montelukast, zafirlukast, and pranlukast). However, results of pharmacoepidemiologic studies suggest that the association between this class of asthma medications and the development of EGPA is likely confounded by the severity of the asthma associated with EGPA.¹¹⁹ As is the case with GPA and MPA, a possible link also exists between EGPA and exposure to silica.¹⁰¹

Immunoglobulin A vasculitis (Henoch-Schönlein purpura)

IgA vasculitis is the most common vasculitis encountered in children in Western countries. Its annual incidence is estimated at between 6.1 and

26.7 per 100,000 children.¹²⁰ These studies suggest that IgA vasculitis is more frequent among children of Asian ancestry (24 per 100,000 infants per year) than in white children (17.8 per 100,000 infants per year) or black children (6.2 per 100,000 infants per year).¹²¹ IgA vasculitis is much rarer in adults than in children, with an annual incidence of 1.1 to 1.8 per 100,000 adults.¹²⁰

A genetic predisposition for IgA vasculitis is suggested by the unequal ethnic distribution and by the association of IgA vasculitis with HLA-DRB1*01, DRB1*11, B35, and A11; the familial Mediterranean fever (MEFV) gene; and the angiotensin-converting enzyme insertion/deletion gene.¹²⁰

Among environmental factors, infections are the leading presumed cause of IgA vasculitis. IgA vasculitis occurs more readily during the winter¹²² and is frequently preceded by an upper or lower airway infection. Several viral and bacterial agents have been implicated in the etiology of IgA vasculitis, but none seems to be the universal cause.¹²⁰ Antigenic stimulations in response to medications, toxins, or food products have been described as preceding the onset of IgA vasculitis,¹²³ but this remains to be confirmed and is not consistently supported by epidemiologic surveys.¹²⁰ In adults, an association of IgA vasculitis with cancers has been described, with a relative risk of concurrent or preceding cancer of 5.3 among patients with IgA vasculitis compared with a matched control group.¹²⁴

Vasculitides affecting vessels of various size

Behçet disease

The epidemiology of Behçet disease (BD) is characterized by a striking geographic disparity with more frequent occurrences in an area spanning from East Asia to the Mediterranean Sea. Therefore BD is sometimes also called the *Silk Road disease*, but the idea that the environmental or genetic cause of BD might have been disseminated throughout this ancient trade route is hypothetical.

Table e153.5 summarizes the many prevalence studies conducted in BD. The highest prevalence of BD has been reported for areas in Turkey, with estimates ranging from 20 to 420 per 100,000 inhabitants.¹²⁵ Studies carried out in populations in Southeast Asia and the Middle East show a prevalence between 2.1 and 120 per 100,000 inhabitants.¹²⁵ In the United States and in Western European countries, prevalence of BD is much lower, with rates between 0.27 and 7.50 per 100,000 inhabitants.¹²⁵⁻¹²⁷

Several studies have addressed the question of risk of BD in migrant populations. Among Turks living in West Berlin, Germany, the prevalence of BD is approximately 40 times higher than in their peers of German descent.¹²⁸ Similarly, in Paris, France, BD is approximately 17 times more frequent among people of Northern African background than among the population with French or other European origins,¹²⁹ and in Sweden it is 7 times more frequent among non-Swedish individuals.¹²⁶ Although a microenvironmental or socioeconomic factor cannot be excluded, these observations support the view that genetic factors play a central role in the development of BD.

There are additional lines of evidence to support the idea that genetic factors are critical in determining susceptibility to BD, including a high familial recurrence rate,^{129,130} concordance for BD between monozygotic twins,^{131,132} and the phenomenon of “genetic anticipation.”¹³³ For pediatric BD, results of a segregation analysis are in keeping with a possible autosomal recessive inheritance pattern.¹³⁴ Additionally, the HLA class I allele B51 is a well-established genetic marker tightly associated with BD.¹³⁵ A meta-analysis found that this allele is carried by 34% to 64% of patients and increases the risk of developing BD by a factor of 5.8.¹³⁵ The results of genomewide association studies further suggested *IL23R-IL12RB2*, *IL10*,^{136,137} *CCR1*, and *STAT4*¹³⁸ as susceptibility loci for BD.

In contrast to the effect of genetic factors, the potential role of environmental determinants in the development of BD remains poorly studied, although infectious causes have been proposed.¹³⁹

Current status of epidemiologic research in the vasculitides

In spite of their rarity, which considerably hampers the conduct of large-scale studies, there has been much progress in the field of epidemiologic research for several of the vasculitides. These studies have helped advance hypotheses regarding the etiologies of many vasculitides. It now seems clear that the different entities have different underlying pathogenic mechanisms which combine, to various extents, with specific genetic backgrounds and environmental factors. Further epidemiologic studies and large-scale genetic association studies will help discern the relative contributions and interactions of genetics and environment to the pathogenesis of these diseases and help unravel the relationships among the individual vasculitides and between the vasculitides and nonvasculitic disorders.

Biology and immunopathogenesis of vasculitis

■ CEES G.M. KALLENBERG

- The endothelium is an active player in inflammatory processes in general and in the pathogenesis of vasculitis in particular.
- Cytokine-induced endothelial cell activation and leukocyte-endothelium interaction are coordinated processes underlying differential leukocyte recruitment to sites of inflammation.
- Immune complex formation and deposition underlie the small-vessel vasculitides in immunoglobulin A vasculitis (Henoch-Schönlein purpura), anti-glomerular basement membrane disease, cryoglobulinemic vasculitis, and hypocomplementemic urticarial vasculitis.
- Clinical and experimental data suggest but do not prove that antineutrophil cytoplasmic antibodies (ANCA) directed against proteinase 3 and myeloperoxidase are pathogenic in the ANCA-associated small-vessel vasculitides.
- Cell-mediated immunity—in particular, a helper T type 1 and helper T type 17 CD4+ T-cell response to as yet undefined antigen(s)—is the major pathogenic event in the medium- and large-vessel vasculitides.

INTRODUCTION

Vasculitis is a condition characterized by inflammation of blood vessels. Its clinical manifestations depend on the location and size of the involved vessels as well as on the nature of the inflammatory process. The vasculitides are localized or systemic diseases with a variable clinical expression. At the Chapel Hill Consensus Conference (CHCC) in 1993 a classification of vasculitides was proposed based largely on the size of the vessels involved, the histopathologic features of the lesions, and clinical findings.¹ By consensus, definitions were proposed for the individual diseases, but it was not the aim of the conference to develop classification criteria (see Chapter 153). Nevertheless, these definitions have been used since then for classifying vasculitis into specific categories. Recently, the nomenclature of the vasculitides has been revised, with inclusion of various conditions not mentioned in the original CHCC nomenclature and an attempt to classify vasculitides also based on underlying condition and probable etiology (Box 154.1).²

As mentioned, vasculitis concerns inflammatory reactions of the blood vessel wall. The vascular endothelium, being at the interface of the circulating bloodstream and the structural components of vascular and perivascular tissue, plays a major role in vasculitis. Cells from the innate and adaptive immune system have to adhere to and pass the endothelium to evoke inflammation in the vessel wall. The endothelium is an active player in this process. Endothelial cells differ in morphology and function depending on their location in the body. Macrovascular endothelial cells are different from microvascular endothelial cells, and various artery-derived endothelial cells are not identical to venous endothelial cells. Because various forms of vasculitis differ in their involvement of the vascular tree, characteristics of the respective endothelia may be relevant for our understanding of the systemic vasculitides.

Therefore, first a discussion is presented of the role of endothelial cells in inflammation. Next, the immunopathogenesis of the major vasculitides is discussed; that is, the vasculitides of the large and medium-sized vessels in which immune deposits are generally absent, the small-vessel vasculitides characterized by immune deposits, and the so-called pauci-immune small-vessel vasculitides that are frequently associated with antineutrophil cytoplasmic autoantibodies (ANCA).

THE ENDOTHELIUM IN INFLAMMATION

The endothelium constitutes a single layer of cells that covers the inner side of blood vessels. It functions as a passive lining of the vasculature and is also actively involved in many physiologic and pathophysiologic processes. The endothelium is not a homogeneous layer of cells throughout the body, but its characteristics and functions differ depending on the size and location of the vessels. In addition, it may change in function and activity after contact with stimuli that are generated locally or systemically.

Larger blood vessels consist of endothelial cells, smooth muscle cells, connective tissue, and elastic elements. The endothelium in these vessels actively participates in the regulation of vascular tone, which determines blood flow to specific organs. Vasodilating effects mostly originate from the production of prostacyclin and nitric oxide by endothelial cells, whereas vasoconstriction is brought about in large part by endothelin-1 and arachidonic acid metabolites, in particular thromboxane A₂ and prostaglandin H₂.³ Particular attention has been paid to dysfunction of endothelial cells in regulating vascular tone as an early manifestation of atherosclerosis.⁴ Also in systemic autoimmune diseases, including systemic vasculitis, endothelial cell dysfunction has been implicated as a major factor underlying early atherosclerosis in these diseases.⁵ *In vitro* studies of endothelial cell function in health and disease using human umbilical vein endothelial cells are frequently used as a model for macrovascular endothelium or for endothelium in general. Their characteristics and functions are not always representative of endothelial cell function *in vivo*. Nevertheless, studies on human umbilical vein endothelial cells have contributed greatly to our knowledge of the endothelium. Presently, microvascular endothelial cells of a different origin (e.g., glomerular endothelial cells) are available for *in vitro* studies and may be more relevant for the investigation of endothelial function in specific disease processes.⁶

In the microvascular bed, endothelial cells reside on a basal lamina with sparsely distributed pericytes around them. These pericytes have important functions in maintaining the integrity of the microvasculature. Loss of pericytes results in endothelial hyperplasia and increased permeability of the endothelium.⁷

The endothelium has the following main functions:

- Providing a semipermeable barrier for transport of soluble molecules
- Maintaining hemostatic balances
- Controlling local blood flow (e.g., via nitric oxide and endothelin-1)
- Regulating coordinated recruitment of leukocytes
- Participating in neovascularization

Although the molecular base of these functions differs, changes in these functions occur in a coordinated way upon stimulation, in particular via proinflammatory cytokines, during inflammation.

Endothelial cell activation during inflammation

Local, or sometimes systemic, recruitment of proinflammatory cytokines results in receptor-mediated activation of endothelial cells. The main representatives are tumor necrosis factor- α (TNF- α), interleukin-1 (IL-1), and IL-17. In addition, thrombotic agonists such as thrombin and, less frequently, oxidants and traumatic stimuli can activate endothelial cells. The first step that follows is the rapid translocation of constitutively present P-selectin from storage granules, the so-called Weibel-Palade bodies. The next step is the transcriptionally regulated synthesis of E-selectin, which is expressed on the endothelial cell surface. In a timely coordinated way a number of other adhesion molecules are produced and expressed on the endothelial cell membrane that are differentially involved in the recruitment

BOX 154.1 NAMES FOR VASCULITIDES ADOPTED BY THE 2012 INTERNATIONAL CHAPEL HILL CONSENSUS CONFERENCE ON THE NOMENCLATURE OF VASCULITIDES
Large-vessel vasculitis (LVV)

Takayasu arteritis (TAK)

Giant cell arteritis (GCA)

Medium-vessel vasculitis (MVV)

Polyarteritis nodosa (PAN)

Kawasaki disease (KD)

Small-vessel vasculitis (SVV)

Antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis (AAV)

Microscopic polyangiitis (MPA)

Granulomatosis with polyangiitis (Wegener granulomatosis) (GPA)

Eosinophilic granulomatosis with polyangiitis (Churg-Strauss vasculitis) (EGPA)

Immune complex SVV

Anti-glomerular basement membrane (anti-GBM) disease

Cryoglobulinemic vasculitis (CV)

Immunoglobulin A vasculitis (Henoch-Schönlein purpura) (IgAV)

Hypocomplementemic urticarial vasculitis (anti-C1q vasculitis)

Variable-vessel vasculitis (VVV)

Behçet disease (BD)

Cogan syndrome (CS)

Single-organ vasculitis (SOV)

Cutaneous leukocytoclastic angiitis

Cutaneous arteritis

Primary central nervous system vasculitis

Isolated aortitis

Vasculitis associated with systemic disease

Lupus vasculitis

Rheumatoid vasculitis

Sarcoid vasculitis

Others

Vasculitis associated with probable etiology

Hepatitis C virus-associated cryoglobulinemic vasculitis

Hepatitis B virus-associated vasculitis

Syphilis-associated aortitis

Drug-associated immune complex vasculitis

Drug-associated ANCA-associated vasculitis

Cancer-associated vasculitis

Others

of various subsets of leukocytes (see later). These molecules include vascular cell adhesion molecule 1 (VCAM-1); intercellular adhesion molecule 1 (ICAM-1), ICAM-2, and ICAM-3; and receptors for leukocyte integrins, such as very late antigen 4 (VLA-4).⁸ In addition, endothelially displaced chemoattractants, called *arrest chemokines*, are produced that induce conformational changes in certain leukocyte integrins that allow their interaction with endothelial adhesion molecules.⁹ Besides producing and upregulating adhesion molecules that regulate leukocyte recruitment, endothelial cell-activating stimuli also affect hemostatic balance. In particular, they induce the production and expression of tissue factor by endothelial cells resulting in a procoagulant state during inflammation. During inflammation, proangiogenic factors—that is, vascular endothelial growth factor (VEGF) and fibroblast growth factor 2 (FGF-2)—also are produced that interact with endothelial cells, which results in angiogenesis, particularly during chronic inflammatory responses. Hypoxic conditions at the site of inflammation induce the expression of hypoxia-inducible factor 1 (HIF-1), a transcription factor expressed in many cells that leads to the expression of genes involved in angiogenesis.¹⁰ For this reason, HIF-1 could be a target for treatment in chronic inflammatory diseases.

Several signal-transducing pathways are involved in endothelial cell activation, and insight into these pathways has stimulated the development of drugs that interfere with these pathways.¹¹ The pathways mostly studied *in vitro* are the TNF- α - and IL-1-mediated signal transduction routes. Soluble TNF- α is released as a trimer and interacts with the TNF receptors TNFR1 and TNFR2. TNFR1 is present on endothelial cells. Interaction of TNF- α with TNFR1 results in a cascade of reactions (as shown in Fig. e154.1). Via nuclear factor- κ B activation the endothelial cells express the adhesion molecules E-selectin, ICAM-1, and VCAM-1; the proinflammatory cytokine

IL-6; the polymorphonuclear neutrophil (PMN) recruiting and activating chemokine IL-8; inducible nitric oxide synthase (iNOS); cyclooxygenase-2; and others. At the same time, protective genes are expressed with antiapoptotic and downregulatory activity. This prevents the activated endothelial cells from going into apoptosis.

Nevertheless, activated endothelial cells, probably in an early apoptotic state, may detach and be present in the bloodstream as circulating endothelial cells. Increased levels of circulating endothelial cells have been reported in active cytomegalovirus infection and in different forms of vasculitis. In ANCA-associated vasculitis their level correlates with disease activity.¹² These circulating endothelial cells were also shown to inhibit endothelial progenitor cells and, for this reason, to contribute to vascular damage, because these endothelial progenitor cells play a major role in repairing injured vessels.¹³ Also, endothelial microparticles have been demonstrated in increased numbers in peripheral blood in patients with active vasculitis. These microparticles are released from endothelial cells and express E-selectin; they should be distinguished from platelet microparticles that express CD42a and are also increased in active vasculitis, and from neutrophil microparticles that are released *in vitro* from ANCA-stimulated neutrophils and activate endothelial cells.^{14,15}

In addition to the TNF- α /TNFR1 pathway, IL-1 is also operative in activating endothelial cells. Endothelial cells express one type of receptor for IL-1, the IL-1R, which binds IL-1 α with higher affinity than IL-1 β . IL-1 β is the soluble form of IL-1 derived from biologically inactive pro-IL-1 β by enzymatic cleavage via caspase-1 and next released. The signal transduction routes involved in endothelial cell activation by IL-1 largely follow the pathways described for TNF- α (see Fig. e154.1).

The effects seem synergistic, however. This may be relevant in view of pharmacologic intervention in both pathways—that is, TNF- α - and IL-1-mediated endothelial cell activation—in vasculitis.

Leukocyte-endothelium interaction

Local recruitment of cells participating in the immune response is essential for immune homeostasis. As mentioned earlier, the coordinated upregulation of adhesion molecules on activation of endothelial cells is instrumental in starting an inflammatory reaction. P-selectin, constitutively present in Weibel-Palade granules, is rapidly translocated to the endothelial cell membrane. This allows the first interaction with circulating neutrophils via P-selectin glycoprotein ligand 1 (PSGL-1), the principal ligand for P-selectin on the neutrophil membrane. This interaction results in tethering of the PMN on the endothelial cell surface. This is rapidly followed, within a couple of hours, by transcription and translation of E-selectin, which appears next on the endothelial cell membrane. E-selectin interacts with sialyl Lewis^x on the PMN. This interaction, together with the binding of L-selectin on PMNs to its ligands on activated endothelial cells, results in a state of rolling of PMNs over the endothelial surface (Fig. e154.2). The rolling neutrophil is now locally activated by signaling molecules, produced by the locally activated endothelium, that bind to G protein-coupled receptors on the neutrophil. These molecules include platelet-activating factor, which is rapidly synthesized and has a phospholipid structure, and the chemokines IL-8 and epithelial neutrophil-activating peptide-78, in addition to the arrest chemokines mentioned earlier.⁹ As part of this activation process of PMNs, β_2 integrins, ligands for a group of adhesion molecules that next appear on activated endothelial cells, undergo conformational alterations resulting in changes in avidity and affinity and are now able to interact with these adhesion molecules that 4 to 12 hours after activation appear on the endothelial cell membrane. The β_2 integrins on leukocytes include the CD11a/CD18 and lymphocyte function-associated antigen 1 (LFA-1) complex that interacts with ICAM-1 and ICAM-2 on activated endothelial cells (see Fig. e154.2). Together with VCAM-1, these molecules belong to the immunoglobulin superfamily. VCAM-1 is the ligand for VLA-4, also indicated as the α_4 integrins, which is expressed on lymphocytes. After these latter ligand-ligand interactions, leukocytes adhere firmly to the endothelium in an activated state.⁸

The next step is when the leukocyte squeezes itself through the endothelium into the surrounding tissue where it follows its way guided by chemokine concentration gradients. This process of diapedesis through the endothelium requires active involvement of molecules located at the junctions of endothelial cells. At least six molecules are involved in junctioning two endothelial cells by homophilic interaction. These include vascular endothelial cell-specific cadherin (VE-cadherin); the junction adhesion molecules JAM-A, JAM-B, and JAM-C; platelet-endothelial cell adhesion molecule-1 (PECAM-1); and CD99.¹⁶ Partial redistribution of these adhesion molecules induced by cytokine stimulation of endothelial cells loosens the junctions and allows the leukocyte to enter the space between the

Fig. e154.1 The activation of interleukin-1 (IL-1) and tumor necrosis factor- α (TNF- α) leads to the expression of proinflammatory genes, including those for cell adhesion molecules, cytokines, and chemokines, as well as cell survival genes. Several pathways result in the activation of the transcription factor nuclear factor- κ B (NF- κ B). At the same time, antiapoptotic signals are generated that prevent apoptosis of the activated endothelial cell. COX-2, cyclooxygenase-2; IKK, I κ B kinase; I κ B, inhibitor of NF- κ B; IRAK, IL-1 receptor-associated kinase; mRNA, messenger RNA; NEMO, NF- κ B essential modulator; NIK, NF- κ B-inducing kinase; PI3-K, phosphatidylinositol 3'-kinase; PKC, protein kinase C; ROS, reactive oxygen species; TRAF2, TNF receptor-associated factor 2. (From Kuldo JM, Ogawara KI, Werner N, et al. Molecular pathways of endothelial cell activation for [targeted] pharmacologic intervention in chronic inflammatory diseases. *Curr Vasc Pharmacol* 2005;3:11-39.)

Fig. e154.2 The four distinct steps in adhesion that leukocytes must undergo to accumulate in a blood vessel are shown at the top of the diagram. Also shown are the predominant molecular determinants of each step with respect to leukocytes (middle of the diagram) and endothelial cells (bottom of the diagram). The arrows in the middle portion indicate the various interactions possible between molecules. Leukocytes in the bloodstream (the graduated set of arrows at the top of the diagram) symbolize the laminar flow profile in blood vessels, where the velocity of blood is fastest in the center and approaches zero at the vessel wall) become tethered to endothelial cells and roll slowly downstream. Tethering is greatly facilitated by leukocyte receptors that occur at high density on the tips of microvillous surface protrusions (L-selectin, P-selectin glycoprotein ligand 1 [PSGL-1], and α_4 integrins), whereas subsequent rolling is not influenced by the topography of adhesion receptors. The most efficient tethering molecules are L-selectin and P-selectin. L-selectin recognizes sulfated sialyl Lewis^x (sLe^x)—like sugars, called *peripheral-node addressin* (PNAd), in high endothelial venules. L-selectin also interacts with other ligands on inflamed endothelial cells (not shown) and with PSGL-1 on adherent leukocytes (indicated by the dashed arrow). The binding of PSGL-1 to L-selectin and P-selectin requires an sLe^x-like sugar to be close to an N-terminal motif containing three tyrosines (Y) that must be sulfated. E-selectin can also interact with PSGL-1, but it does not require tyrosine sulfation. E-selectin also recognizes other sLe^x-bearing glycoconjugates. E-selectin and the α_4 integrins can tether some leukocytes, but their predominant function is to reduce the velocity of rolling. Rolling leukocytes respond to chemoattractants on endothelial cells because they express specific receptors with seven transmembrane domains (7 TMR), which transmit intracellular signals through G proteins. The most prominent chemoattractants that bind to 7 TMR are listed in the figure. Some of these molecules, such as chemokines, are presented on the endothelial surface; others are secreted or diffuse freely into the vessel lumen. The activating signal induces rapid activation of β_2 integrins, α_4 integrins, or both, which bind to members of the endothelial immunoglobulin superfamily. The α_4 integrins can mediate activation-independent rolling interactions as well as arrest rolling leukocytes. However, the latter function requires the activation of α_4 integrins (illustrated by the more open conformation of the integrin heterodimer, compared with that of α_4 integrins that mediate rolling). C5a, activated C5; ICAM-1, ICAM-2, intercellular adhesion molecules 1 and 2; LTB₄, leukotriene B₄; MAdCAM-1, mucosal addressin cell adhesion molecule type 1; PAF, platelet-activating factor; VCAM-1, vascular cell adhesion molecule 1. (Reproduced with permission from von Adrian UH, Mackay CR. T-cell function and migration. Two sides of the same coin. *N Engl J Med* 2000;343:1020-34.)

endothelial cells. It should be mentioned that PECAM-1, CD99, JAM-A, and JAM-C are found also on leukocytes and that homophilic interactions between leukocytes and endothelial cells certainly play a role in transmigration of leukocytes as well. This process of transmigration is an active process also for the endothelial cell because calcium influx in endothelial cells is required for effective diapedesis. Recent data suggest that, in addition to engaging in this so-called paracellular transmigration, leukocytes may also follow a transcellular route of transmigration in which cytoskeletal remodeling and membrane fusion events play a major role.¹⁷

Leukocyte-endothelial cell interaction preferentially occurs in postcapillary venules. It is noteworthy that many forms of small-vessel vasculitis are manifested by leukocytoclastic vasculitis localized in postcapillary venules, particularly in the skin. Here, PMNs do not pass the vascular wall but become fully activated, followed by apoptosis and necrosis within the vessel wall. The role of immune complexes and ANCAs in this process is discussed later in the section on small-vessel vasculitis.

Endothelium, coagulation, and inflammation

Tissue factor is upregulated in endothelial cells activated by, among others, proinflammatory cytokines. Tissue factor is a transmembrane protein that initiates coagulation. It can be expressed by malignant cells and macrophages as well and plays a role in angiogenesis, particularly in tumor development. In the resting state, endothelium has antithrombotic characteristics based on the expression of thrombomodulin, heparan sulfate proteoglycans that bind and activate antithrombin III, prostacyclin, ecto-adenosine diphosphatase, and receptors for fibrinolytic agents, such as plasminogen and tissue plasminogen activator. One of the first steps in endothelial cell activation is the translocation of P-selectin from the Weibel-Palade bodies to the membrane of endothelial cells. Interaction of P-selectin with PSGL-1 on leukocytes induces the upregulation of tissue factor, which initiates the coagulation cascade. In addition, it leads to the formation of platelet-leukocyte aggregates and the production of procoagulant microparticles that are tissue factor positive as well. Furthermore, P-selectin on activated platelets contributes to the recruitment of these microparticles to thrombi. Thus P-selectin expression plays a major initiating role in the development of the procoagulant state of endothelium in inflammation. The prothrombotic state of activated endothelial cells is further highlighted by the loss of thrombomodulin and heparan sulfate proteoglycans. Indeed, elevated levels of serum thrombomodulin occur in many forms of vasculitis and have been proposed as markers of disease activity.

Damage and repair: angiogenesis

In chronic inflammatory conditions such as rheumatoid arthritis angiogenesis is part of the inflammatory process.¹⁸ Three different processes are involved in angiogenesis: angiogenic sprouting, intussusceptive growth, and seeding of endothelial progenitor cells in newly formed blood vessels.

Sprouting from endothelial cells occurs in the presence of hypoxemia. It first requires degradation of the endothelial cell basement membrane via production of metalloproteinases and gelatinases by the activated endothelial cell. Sprouting endothelial cells need a new basement membrane as well as pericytes for their further development. Locally produced platelet-derived growth factor (PDGF) and transforming growth factor- β are major players in this process. Endothelial cell proliferation itself is under the control of angiogenic factors called *angiopoietins*. The best characterized are VEGF and FGF. Both factors are produced by a variety of cells, and HIF-1 (see earlier) is the major transcription factor involved.¹⁰ Receptors for VEGF, which itself occurs in various forms, are expressed on endothelial cells but also on monocytes and smooth muscle cells. Binding of VEGF to its receptor on the endothelial cell leads to a cascade of signal transduction steps that finally result in vessel hyperpermeability via production of platelet-activating factor, cell proliferation with inhibition of apoptosis after activation, and actin reorganization and cell migration.¹⁹ As mentioned earlier, endothelial progenitor cells also play a role in neovascularization and repair. Endothelial progenitor cells, derived from stem cells, constitute 0.01% of peripheral blood mononuclear cells and are characterized by the surface markers CD34 and VEGF receptor type 2, although there is still controversy on their characterization.²⁰ Under the influence of several factors, among which are VEGF, granulocyte-macrophage colony-stimulating factor, erythropoietin, tissue ischemia, and, interestingly, hydroxymethylglutaryl-coenzyme A reductase inhibitors, these cells can be mobilized and induced to proliferate. Different sources of endothelial progenitor cells have been identified, and their role in chronic inflammatory conditions is not yet well defined,^{11,19} although they have been suggested to contribute to vascular repair in vasculitis.¹⁴

IMMUNOPATHOGENESIS OF SMALL-VESSEL VASCULITIDES

Based on the 2012 CHCC classification,² the small-vessel vasculitides show vasculitic involvement of arterioles, capillaries, or venules. Larger vessels may be involved as well. Within this category two groups are identified: the immune complex-mediated small-vessel vasculitides and the ANCA-associated vasculitides. The former group encompasses IgA vasculitis (Henoch-Schönlein purpura) and cryoglobulinemic vasculitis as the two most prevalent conditions and, in addition, anti-glomerular basement membrane (anti-GBM) disease and hypocomplementemic urticarial vasculitis (anti-C1q vasculitis); the second group consists of granulomatosis with polyangiitis, microscopic polyangiitis, and eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome).

Immune complex-mediated small-vessel vasculitides

Since 1970, immune complexes have been considered as pathogenic factors in many forms of vasculitis. In some of the vasculitides associated with probable etiology (see Box 154.1) in particular, immune complexes consisting of microbial antigens or drugs and their cognate antibodies may be operative in pathogenesis. Although immune deposits, that is, immunoglobulin and complement, have been detected by direct immunofluorescence in vessel walls, the antigens supposedly involved in the complexes have been identified only in a minority of cases. Nevertheless, small-vessel vasculitis in the presence of immune deposits should always raise suspicion of an underlying disorder, either one of the connective tissue diseases or an infectious disorder. In particular, infective endocarditis may mimic idiopathic small-vessel vasculitides. Chronic immune stimulation during infections may even result in polyclonal B-cell stimulation with production of autoantibodies such as rheumatoid factor (RF), antinuclear antibodies, and ANCA, the last frequently but not always of unspecified antigenic specificity. Within the spectrum of idiopathic vasculitides, the 2012 CHCC classification defined IgA vasculitis, anti-GBM disease, cryoglobulinemic vasculitis, and hypocomplementemic urticarial vasculitis as disorders that are characterized by the presence of immune deposits within the vessel wall.

Immunoglobulin A vasculitis (Henoch-Schönlein purpura)

IgA vasculitis is defined by the CHCC as “a vasculitis with IgA1-dominant immune deposits affecting small vessels (predominantly capillaries, venules, or arterioles); often involves skin and gastrointestinal tract and frequently causes arthritis; glomerulonephritis indistinguishable from IgA nephropathy may occur.”²² This definition implies that IgA1-containing complexes are the primary pathogenic factor in this disease. Indeed, deposition of polymeric IgA1 in combination with complement C3 has been found in capillaries and postcapillary venules in skin, gastrointestinal tract, and glomeruli in IgA vasculitis (Fig. 154.1). Within the kidney, IgA1 deposits are found in the glomerular capillary wall and in the mesangium, with the mesangium being the main location of IgA1 deposits. Data relating to the pathogenesis of IgA vasculitis are derived also from studies of IgA nephropathy because no major biologic differences have been found between the two diseases.^{21,22} The origin of polymeric IgA1 that is deposited in the vessel wall in IgA vasculitis has not been fully clarified. Serum IgA consists mainly of monomeric IgA1, and IgA from mucosal surfaces consists of 60% of polymeric IgA2 (two IgA2 molecules connected by a J protein). Total serum IgA level is increased in around 50% of patients with IgA vasculitis, and this increase involves both monomeric IgA1 and polymeric IgA1.^{21,22} Increase in IgA level has been related to increased production due to stimulation of the mucosal immune system. However, no consistent antigen(s) have been detected in the immune deposits. Otherwise, precipitation and induction of relapse of IgA vasculitis has been associated with microbial infections, drugs, and food antigens.²²

Whether primary disturbances in immunoregulation underlie increased IgA production in IgA vasculitis is not clear. Besides increased production, impaired clearance of IgA1 has been demonstrated. It should be noted that high levels of IgA1 in themselves do not result in IgA vasculitis. In patients with IgA1 myeloma or human immunodeficiency virus infection with increased IgA levels, precipitation of IgA vasculitis has not been observed. Abnormal glycosylation of IgA, particularly in the hinge region of the molecule, has been implicated as a causal factor for abnormal clearance and formation of complexes of IgA with fibronectin, lectin, IgG, and IgA1 itself (resulting in polymeric IgA1). Abnormal glycosylation of IgA is particularly present in patients with nephritis as part of IgA vasculitis.²¹ It has been suggested that this abnormal glycosylation constitutes neopeptides on IgA1

Fig. 154.1 Nephritis in immunoglobulin A (IgA) vasculitis (Henoch-Schönlein nephritis). (a) Renal biopsy was performed in a 45-year-old woman with recurrent cutaneous vasculitis and episodes of gastrointestinal vasculitis of 2 years' duration because of recent-onset erythrocyturia and severe proteinuria. Specimen shows a focal and segmental extracapillary crescentic glomerulonephritis of recent origin (silver methenamine, hematoxylin-eosin, $\times 50$). (b) Staining with monoclonal anti-IgA1 antibodies shows diffuse glomerular and granular deposits in the mesangia and locally in the capillary wall. Inset: staining for C3 shows a similar pattern (immunofluorescence, anti-IgA, $\times 125$).

that induce IgG class antibodies that complex with abnormally glycosylated IgA. These complexes could be pathogenic factors in nephritis as part of IgA vasculitis and IgA nephropathy by activating mesangial cells²¹ (Fig. 154.2). A genetic basis of aberrant glycosylation has been suggested.²³

How do increased levels of IgA and/or abnormally structured IgA result in immune complex-mediated vasculitis? Both immune complex deposition from the circulation and *in situ* complex formation may play a role, because in 50% of patients circulating immune complexes are not demonstrated to be present. Polymeric IgA1 can interact with Fc α receptors on mesangial cells and activate these cells, which results in mesangial glomerulonephritis. Otherwise, subendothelial deposition or *in situ* complex formation can result in complement activation either via the alternative pathway with deposition of properdin and/or via the mannan-binding lectin pathway. Coprecipitation of IgG and/or IgM may incidentally lead to complement activation via the classical pathway as well. Subendothelial deposition results in endocapillary proliferation and crescent formation in the kidneys.²¹

Leukocytoclastic vasculitis in the skin and gastrointestinal tract in IgA vasculitis is induced by subendothelial immune deposition, which results in endothelial activation with upregulation of adhesion molecules. Recruitment of neutrophils is further stimulated via production of chemokines such as IL-8 by activated endothelial cells. Polymeric IgA or IgA complexes may activate these neutrophils additionally.

Anti-glomerular basement membrane disease

Anti-GBM disease is defined by the CHCC as “vasculitis affecting glomerular capillaries, pulmonary capillaries, or both, with basement membrane deposition of anti-basement membrane autoantibodies; lung involvement causes pulmonary hemorrhage, and renal involvement causes glomerulonephritis with necrosis and crescents.”²² The clinical syndrome of pulmonary hemorrhage and necrotizing crescentic glomerulonephritis is designated also as *Goodpasture syndrome*. This syndrome can be due to anti-GBM disease but can also be present in ANCA-associated vasculitis and other forms of small-vessel vasculitis. For this reason the term *renopulmonary syndrome* is preferred to avoid the use of *Goodpasture syndrome* as synonymous with anti-GBM disease.

The autoantibodies in anti-GBM disease are directed against the C-terminal globular (NC1) domain of a tissue-specific type IV collagen chain, the $\alpha 3$ chain, or $\alpha 3(\text{IV})\text{NC1}$ in abbreviation.²⁴ The same epitopes are recognized in all patients. In direct immunofluorescence testing of renal tissue from patients with anti-GBM disease a linear pattern of GBM staining is seen for IgG and complement C3. The pathogenicity of these autoantibodies has been demonstrated by eluting IgG class antibodies from kidneys of patients with anti-GBM disease and injecting the eluates in monkeys. This resulted in deposition of the antibodies and complement at the GBM and glomerulonephritis but without crescent formation. Further studies, both in experimental animals and in humans, demonstrated that cellular immunity as well is required for lesion development, including crescent formation in human anti-GBM disease.²⁵

MAJOR STEPS IN THE PATHOGENESIS OF NEPHRITIS AS PART OF IGA VASCULITIS AND IGA NEPHROPATHY

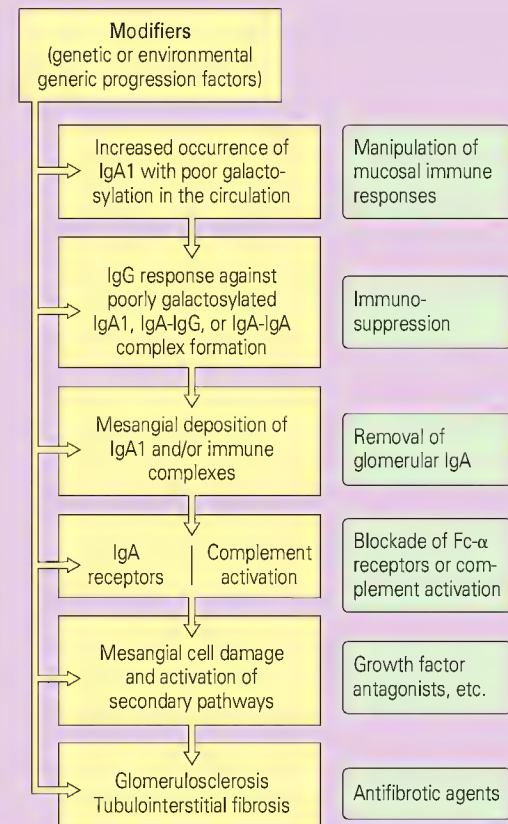

Fig. 154.2 Each of the key steps (center) in the pathogenesis of nephritis in immunoglobulin A (IgA) vasculitis and IgA nephropathy likely is affected by potent genetic or environmental modifiers. Potential therapeutic consequences are shown on the right. (Reproduced with permission from Floege J. The pathogenesis of IgA nephropathy: what is new and how does it change therapeutic approaches? *Am J Kidney Dis* 2011;58:992-1000.)

Cryoglobulinemic vasculitis

Cryoglobulinemic vasculitis is defined according to the 2012 CHCC classification as “vasculitis with cryoglobulin immune deposits affecting small vessels (predominantly capillaries, venules, or arterioles) and associated with cryoglobulins in serum; skin, glomeruli and peripheral nerves are often involved.”²

The main element in the pathogenesis of this disorder is the presence of cryoglobulins that are cold-precipitable immunoglobulins. Three types of cryoglobulins are detectable:

Type I, found in 10% to 15% of patients, consists of monoclonal IgM-RF and originates in the context of a lymphoproliferative or myeloproliferative disease.

Type II, occurring in 50% to 60% of patients, consists of monoclonal IgM-RF and polyclonal IgG.

Type III, found in 30% to 40% of patients, consists of polyclonal IgM-RF and polyclonal IgG.

Type II and type III cryoglobulins are collectively referred to as *mixed cryoglobulins*. These mixed cryoglobulins have been detected during chronic bacterial and viral infections and as part of (systemic) autoimmune diseases, in particular in Sjögren syndrome. The remaining idiopathic cases are designated as *essential mixed cryoglobulinemia*. It has become apparent, however, that many cases of essential mixed cryoglobulinemia are related to hepatitis C virus (HCV) infection.²⁶ The percentage of HCV-related cases differs among geographic areas, ranging from 40% to 100%, with a 90% association in the Mediterranean countries.

The etiopathogenesis of essential mixed cryoglobulinemia without HCV infection has not been clarified, but polyclonal B-cell activation and/or antigen/superantigen-driven B-cell activation have been suggested. More insight has been obtained into the etiopathogenesis of mixed cryoglobulinemia associated with HCV infection. Various explanations have been proposed for HCV-induced cryoglobulin production. The HCV envelope protein E2 can bind to CD81, which is present on hepatocytes and lymphocytes as well, and trigger a polyclonal B-cell response. Also, IgG with anti-HCV reactivity can induce IgM-RF molecules with a particular cross-idiotype. At that stage, low-titer type III cryoglobulins are present. Next, a single dominant clone-producing monoclonal IgM-RF emerges, which results in the production of high-titer type II cryoglobulins. This event can result in progression into a malignant B-cell lymphoma. B-cell proliferation particularly occurs within the CD5-positive subtype, which is a dominant B-cell type in other autoimmune diseases as well. Thus it seems that IgG anti-HCV core antibodies select a particular RF repertoire. This explains the presence of HCV-related proteins in the skin blood vessels of patients with type II mixed cryoglobulinemia.²⁷

The clinical manifestations of (HCV-related) mixed cryoglobulinemia are purpura, arthritis/arthralgia, peripheral neuropathy, and nephritis. The full-blown spectrum of the disease is seen in association with type II cryoglobulins. HCV proteins are present in the dermis and epidermis, but vascular damage develops in the presence of IgM and IgG molecules only, in

conjunction with complement deposition. Endothelial activation with upregulation of adhesion molecules attracts neutrophils, which leads to leukocytoclastic vasculitis. Within the kidney, subendothelial cryoglobulin deposition results in membranoproliferative glomerulonephritis type I, occurring in 20% to 30% of patients (Fig. 154.3). Here also, HCV core proteins can be detected. Vasculitis of small- and medium-sized renal arteries occurs in one third of patients. Focal, immune complex-mediated glomerulonephritis may occur in type III cryoglobulinemia and is much milder than in type II cryoglobulinemia. Neuropathy has been considered to result from vasculitis of the vasa nervorum.

Hypocomplementemic urticarial vasculitis (anti-C1q vasculitis)

Hypocomplementemic urticarial vasculitis is defined by the 2012 CHCC as “vasculitis accompanied by urticaria and hypocomplementemia affecting small vessels and associated with anti-C1q antibodies; glomerulonephritis, arthritis, obstructive pulmonary disease, and ocular inflammation are common.”² Lesions show leukocytoclastic vasculitis with deposition of immunoglobulins and complement. The disease can be idiopathic or associated with systemic autoimmune diseases such as systemic lupus erythematosus and Sjögren syndrome; infectious diseases, in particular hepatitis B and C; use of medication; malignancies; and other conditions. Autoantibodies to the collagenous part of C1q are invariably present in patients with the idiopathic variety of the disease. Anti-C1q autoantibodies are, however, far from specific for the disease, and their primary pathogenic role in hypocomplementemic urticarial vasculitis has not been proven.²⁸

Antineutrophil cytoplasmic antibody-associated vasculitides

Unlike in IgA vasculitis and cryoglobulinemic vasculitis, in ANCA-associated vasculitides—that is, granulomatosis with polyangiitis (GPA), microscopic polyangiitis (MPA), and eosinophilic granulomatosis with polyangiitis (EGPA)—immune deposits are generally, but not always, absent at the lesional sites. These disorders are characterized by the presence of autoantibodies against cytoplasmic constituents of neutrophils and monocytes, designated as ANCAs (Fig. 154.4). ANCAs in the vasculitides are directed either against proteinase 3 (PR3), a third serine protease besides elastase and cathepsin G that is found in neutrophil granules, or against myeloperoxidase (MPO).^{29,30} Three lines of evidence suggest, but do not prove, that PR3-ANCAs and MPO-ANCAs are involved in the pathogenesis of their associated disorders.

First, PR3-ANCA and MPO-ANCA are closely associated with GPA, MPA, and EGPA. Diagnostic sensitivity and specificity, as derived from several studies, are given in Table 154.1. In EGPA, MPO-ANCAs are associated with typical vasculitic lesions, whereas in the absence of ANCAs, eosinophilic infiltration, generally without apparent small-vessel vasculitis, predominates.³¹ Furthermore, increase in levels of ANCAs has been shown to precede relapses of the associated disease. The predictive value of an increase in ANCA titer in patients with GPA as measured by

Fig. 154.3 Essential type II cryoglobulinemia. (a) Diffuse proliferation of mesangial cells and subendothelial deposition of eosinophilic material with or without mesangial (matrix) interposition (silver methenamine, hematoxylin-eosin, $\times 125$). (b) Anti-C3 polyclonal antibodies. Diffuse glomerular granular deposition of immune complexes consisting of immunoglobulin G (IgG), IgM, and C1q (not shown) as well as C3 in the mesangial area is seen as well as subendothelial deposition and occasionally intracapillary aggregates (immunofluorescence, $\times 125$).

Fig. 154.4 Staining of cytoplasmic components of ethanol-fixed neutrophils by indirect immunofluorescence using a serum sample from a patient with active antineutrophil cytoplasmic antibody (ANCA)-associated granulomatous vasculitis and antibodies to proteinase 3. (a) A characteristic granular pattern of fluorescence (c-ANCA) is seen, (b) This fluorescence pattern is different from the perinuclear pattern that can be produced by serum samples from patients with antimyeloperoxidase antibodies (p-ANCA).

TABLE 154.1
Disease associations of PR3-ANCA and MPO-ANCA

Disease entity	Sensitivity of	
	PR3-ANCA (%)	MPO (%)
Granulomatosis with polyangiitis	66	24
Microscopic polyangiitis	26	58
Idiopathic crescentic glomerulonephritis	30	64
Eosinophilic granulomatosis with polyangiitis	<5	40

ANCA, antineutrophil cytoplasmic antibody; MPO, myeloperoxidase; PR3, proteinase 3.

indirect immunofluorescence (IIF) was reported as 57% and for PR3-ANCAs measured by enzyme-linked immunosorbent assay (ELISA) as 71%.³² Otherwise, 43% of patients with a rise in ANCAs by IIF and 29% with a rise in PR3-ANCAs by ELISA did not experience relapse.³² These data, however, have not been confirmed in other studies.³³ Also, patients who persistently test positive for PR3-ANCAs after induction of remission have a higher chance of ensuing relapses.³⁰ Thus PR3-ANCAs and MPO-ANCAs are certainly associated with GPA, MPA, and, to a lesser extent, EGPA, but this association, particularly in relation to relapsing disease, is far from absolute. Two other observations support a pathogenic role for ANCA *in vivo*. First, pulmonary hemorrhage and renal involvement were reported in a neonate with MPO-ANCA in cord blood and a mother who had a history of previous MPO-ANCA vasculitis and at the time of delivery had preeclampsia and tested positive for MPO-ANCA.³⁴ Second, a large genomewide association study demonstrated the association of PR3-ANCA with HLA-DP genes as well as with genes encoding for PR3 and α_1 -antitrypsin as well as the association of MPO-ANCA with HLA-DQ genes; these associations were stronger for the autoantibodies than for the associated diseases—that is, GPA and MPA.³⁵

Second, *in vitro* studies showed that ANCAs are able to stimulate neutrophils, primed with low doses of proinflammatory cytokines, to produce reactive oxygen species and release lytic enzymes. In various *in vitro* systems, ANCAs are able to induce adherence of neutrophils to endothelial cells and to stimulate neutrophils to lyse endothelial cells or to induce detachment of these cells. The interaction between ANCAs and neutrophils occurs via binding of their F(ab')₂ fragment to PR3 or MPO expressed on the neutrophil surface as well as by binding of their Fc fragments to Fc γ receptors on the neutrophils. The pathways and signal transduction routes involved in ANCA-induced neutrophil activation have been further elucidated as possible targets for treatment. A percentage of peripheral blood neutrophils express PR3, with or without priming, and this percentage differs among individuals and seems genetically determined. Interestingly, this percentage is higher in patients with GPA than in healthy control subjects, and within a cohort of patients with GPA higher expression is associated with more

frequent relapses. Thus both availability of the autoantigens on the surface of neutrophils, in particular PR3, and the neutrophil activating potential of ANCA appear to be involved in necrotizing vasculitis based on *in vitro* studies.³⁰

The third and strongest argument for pathogenicity of ANCAs is derived from experimental studies in animals. In these studies, an MPO-directed immune response was induced by immunizing MPO-deficient mice with mouse MPO. IgG or splenocytes of these mice were transferred into immunodeficient mice or wild-type mice. This resulted in the development of (focal) necrotizing glomerulonephritis and pulmonary capillaritis, which was augmented by the simultaneous injection of lipopolysaccharide (Fig. 154.5). Furthermore, the alternative pathway of complement has been demonstrated to be an essential factor for lesion development because mice deficient in factor B or factor C5 of the complement system did not develop lesions. This model strongly suggests a direct pathogenic effect of MPO-ANCAs. Also, a rat model of anti-MPO-associated vasculitis demonstrated the *in-vivo* potential of anti-MPO to interfere with leukocyte-endothelial interaction and to cause microvascular damage. However, an approach comparable to that described earlier for anti-MPO-associated vasculitis but using PR3-deficient mice did not result in necrotizing vasculitis but in augmentation of a locally induced inflammatory response only.³⁶ A more recent model,^{36a} in which human hematopoietic stem cells were injected into immunodeficient mice followed by injection with human PR3-ANCA, did result in glomerulonephritis and pulmonary capillaritis in part of the mice but not in granulomatous lesions, which are characteristic for PR3-ANCA associated GPA.

In summary, although it is difficult to prove, the currently available data certainly suggest that ANCAs are pathogenic (Fig. 154.6).

Recently, a new autoantibody has been described in patients with pauci-immune necrotizing crescentic glomerulonephritis (NCGN), the renal manifestation of ANCA-associated vasculitis.³⁷ This antibody is directed against lysosomal membrane protein-2 (Lamp-2) and seems both sensitive and specific for pauci-immune NCGN, although these data are still controversial.³⁸ Anti-Lamp-2 antibodies are able to induce pauci-immune focal NCGN in an animal model. Furthermore, an epitope of human Lamp-2 shows 100% homology with a bacterial adhesin from gram-negative bacteria.³⁷ These data suggest that bacterial peptides may induce a pathogenic autoantibody that results in the renal manifestations of ANCA-associated vasculitis.

Immunopathogenesis of major small-vessel vasculitides

Granulomatosis with polyangiitis

The cause of GPA is not known. The initial phase of the disease is frequently characterized by ongoing (destructive) inflammation in the upper airways. This localized form of the disease may persist, but the disease may also progress to (or directly manifest as) a generalized form. Relapses also frequently start with otorhinolaryngologic symptoms, and grumbling disease is mostly apparent in this region as well. This suggests that the initial trigger is localized in the upper airways. Friedrich Wegener, after whom the disease

(c) Segmental fibrinoid necrosis with an adjacent small cellular crescent (arrow). (d) Large circumferential cellular crescent (between arrows) completely surrounding a glomerulus. (e) Immunofluorescence microscopy for fibrin showing prominent staining corresponding to segmental necrosis and crescent formation. (f) Immunofluorescence microscopy for IgG showing a paucity of segmental staining corresponding to an area of segmental necrosis. (Masson trichrome staining for light microscopy.) (From Xiao H, Heeringa P, Hu P, et al. Antineutrophil cytoplasmic autoantibodies specific for myeloperoxidase cause glomerulonephritis and vasculitis in mice. *J Clin Invest* 2002;110:955-63, with permission.)

was previously named, considered the disease to be a pathergic reaction to an environmental factor. This factor has not yet been identified, but chronic nasal carriage of *Staphylococcus aureus* is present in 60% of patients with GPA compared with 20% of control subjects and is associated with a relapsing course.³⁹ If this association is based on a causal relationship, it is presently not clear. GPA is strongly associated with the presence of PR3-ANCAs (see Table 154.1). Recently, peptides encoded by RNA that shows complementarity to RNA encoding for PR3 have been shown to induce PR3-ANCAs by as yet unknown mechanisms. Peptides from this so-called complementary PR3 (cPR3) showed homology to several microbial peptides, among which are peptides from *S. aureus*.⁴⁰ Also, other observations connect upper airway inflammation with *S. aureus* carriage and PR3-ANCAs. Analysis of the immunoglobulin gene repertoire as present in granulomatous lesions in the upper airway showed a predominance of V_H³-positive B cells with affinity for both PR3 and the *S. aureus*-derived B-cell superantigen staphylococcal protein A. Thus several lines of evidence suggest that upper airway inflammation with persistence of *S. aureus* may induce germinal center formation with affinity maturation of PR3-ANCA-producing B cells.

PR3-ANCAs are strongly associated with GPA, although MPO-ANCAs may occur as well (see Table 154.1). Within cohorts of patients with ANCA-associated vasculitis, patients who test positive for PR3-ANCAs show more granulomatous inflammation, more widespread organ involvement, and a faster decline in renal function than patients who test positive for MPO-ANCA. In addition, data from animal experiments suggest a direct pathogenic effect of MPO-ANCAs but not of PR3-ANCAs (see earlier). Furthermore, the genetic background of PR-ANCA is different from that of MPO-ANCA (see earlier). Thus, both clinically and experimentally, PR3-ANCA-associated disease differs from MPO-ANCA-associated vasculitis. However, this clinical distinction between PR3-ANCA- and MPO-ANCA-associated disease is far less apparent in cohorts from east Asian countries.

The granulomatous inflammatory lesions in GPA indicate involvement of cellular immune responses. Although the targets of these immune

responses are not yet known, persistent T-cell activation with predominance of effector memory T cells is present in GPA also during remission. Relapses coincide with an increase in levels of soluble IL-2R, which reflects increase in T-cell activation. In terms of cytokine production, type 1 helper T (Th1) cells seem to predominate, although this has not been consistently found. More recent studies show that effector memory T cells, probably with a cytokine pattern consistent with Th17 cells, are continuously present also during quiescent disease and localize in target tissues such as the kidneys when the disease becomes active. Furthermore, functional deficiencies in regulatory T cells have been suggested in GPA. In conclusion, current data suggest an exogenous trigger as the inducing agent in GPA followed by immune activation with generation of PR3-ANCAs as well as effector T cells.^{30,41}

Microscopic polyangiitis

MPA, in contrast to classic polyarteritis nodosa, is an ANCA-associated disease characterized by small-vessel vasculitis with frequent involvement of the kidneys (pauci-immune NCGN) and, somewhat less frequently, the lungs (pulmonary capillaritis). Their combined involvement results in a renopulmonary syndrome. ANCAs are directed against MPO in the majority of patients (see Table 154.1). There is increasing evidence from experimental animal models that MPO-ANCAs are pathogenic, as discussed earlier.³⁶ With respect to the mechanisms involved, a recent rat model of MPO-ANCA-induced renopulmonary syndrome showed that MPO-ANCAs induce leukocyte firm adhesion and transmigration, which leads to microvascular injury. After injection of immunoglobulin fractions with MPO-ANCAs into naive rats, endothelial injury with postcapillary venular hemorrhage was observed.³⁶ All of these data strongly suggest a direct pathogenic role for MPO-ANCAs in MPA based on studies that show similarities between clinical and histopathologic findings in MPA and lesion development in *in-vivo* experimental models. Also, the occurrence of MPA in a neonate born to a mother with MPO-ANCAs strongly suggests that transplacental transfer of IgG-class MPO-ANCAs can induce this disease.³⁴

Fig. 154.6 In antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis (AAV), local infection, such as with *Staphylococcus aureus*, results in priming of neutrophils via proinflammatory cytokines. This results in the surface expression of the ANCA antigens allowing ANCAs to bind to and further activate neutrophils that are rolling along the endothelium. Activation results in firm binding to the endothelium and release of lytic enzymes and reactive oxygen species (ROS), which damage the vessel wall. Also, the alternative pathway of complement is activated with generation of the powerful neutrophil chemoattractant C5a. This amplification loop contributes to the necrotizing inflammation of the vessel wall. (From Chen M, Kallenberg CG. ANCA-associated vasculitides—advances in pathogenesis and treatment. *Nat Rev Rheumatol* 2010;6:653-66, with permission).

Interestingly, anti-GBM antibodies are found in around 30% of patients with MPO-ANCA-associated vasculitis. This subset of patients has more severe renopulmonary disease and a poorer prognosis than patients with MPO-ANCAs only.⁴² The direct pathogenic effect of anti-GBM antibodies has been proven in clinical and experimental studies. In all likelihood, both anti-GBM antibodies and MPO-ANCAs contribute to lesion development in this subset.

Eosinophilic granulomatosis with polyangiitis

Within the spectrum of ANCA-associated vasculitides, ANCAs occur less frequently in EGPA. Around 40% of patients test positive, in most cases for MPO-ANCAs.³¹ The presence of ANCAs in EGPA is associated with small-vessel vasculitis clinically apparent as purpura, mononeuritis multiplex, necrotizing glomerulonephritis, and pulmonary hemorrhage. This suggests that EGPA includes two disease entities, one associated with ANCAs and characterized by small-vessel vasculitis and the other being ANCA negative and characterized by tissue infiltration by eosinophils. In the former subset, pathogenic events follow pathways as mentioned earlier for MPO-ANCA-associated MPA. The latter subset more resembles the hypereosinophilic syndrome in which clonal or T cell-driven polyclonal expansion of eosinophils with tissue infiltration and release of toxic products by these cells plays a major role in pathogenesis.³¹

IMMUNOPATHOGENESIS OF VASCULITIDES OF MEDIUM- AND SMALL-SIZED ARTERIES

Among the vasculitides of medium- and small-sized arteries, classic polyarteritis nodosa and Kawasaki disease are the major disorders.

Polyarteritis nodosa

The 2012 CHCC defined classic polyarteritis nodosa (PAN) as “necrotizing arteritis of medium or small arteries without glomerulonephritis or vasculitis in arterioles, capillaries, or venules, and not associated with ANCA.”²

This definition excludes any vasculitic condition in which arterioles, capillaries, and venules are involved. For this reason, many conditions previously described as PAN are now designated as MPA, which makes classic PAN a very rare disorder. Classic PAN is characterized by segmental necrotizing arterial lesions frequently with microaneurysm formation and resulting in ischemia, infarction, and hemorrhage.⁴³ Not infrequently, it presents as an isolated finding (e.g., as small bowel infarction). Hepatitis B virus (HBV)-related PAN, formerly observed in one third of patients with PAN, is now rare. This condition presents as an acute disease occurring within 6 months of an HBV infection. Abdominal signs, malignant hypertension with renal failure, and orchitis are predominant. The immunopathogenesis of classic PAN, including HBV-related PAN, has been studied to a limited extent. ANCAs are absent; immune deposits are detected particularly in HBV-related PAN. Once viral replication has stopped and seroconversion has occurred, the disease does not progress or relapse.⁴⁴ This strongly suggests that HBV-related PAN is caused by immune complex formation in antigen excess. In HBV-negative PAN, immune deposits are frequently absent, and its immunopathogenesis is presently unclear. Shear stress at arterial bifurcation points may be involved in the location of the lesions and microaneurysm formation.

Kawasaki disease

Kawasaki disease is an acute, self-limiting form of vasculitis occurring in childhood. It starts with fever, conjunctivitis, erythema of the lips and oral mucosa, and cervical lymphadenopathy, together with an acute-phase response. Without treatment, coronary vasculitis with aneurysm formation develops in 25% of patients.⁴⁵ Prompt treatment with intravenous immunoglobulin reduces this percentage to less than 5%. The clinical presentation as well as the epidemiology of the disease strongly suggests an infectious origin, but despite many efforts a particular microbial pathogen has not been identified. A few pathologic observations, obtained from postmortem studies, show endothelial activation with subendothelial infiltration of mononuclear cells, in particular cytotoxic T cells and monocytes/macrophages in the coronary arteries, which are a site of predilection in this

medium-sized artery vasculitis. This contrasts with the fibrinoid necrosis and neutrophil infiltration seen in classic PAN and suggests a viral origin. The finding of oligoclonal IgA-producing plasma cells around inflamed coronary arteries also suggests a microbial cause, more specifically a respiratory virus. Previous studies have pointed toward a role for superantigens in Kawasaki disease. Superantigens are able to cross-link major histocompatibility complex (MHC) molecules on antigen-presenting cells with particular V β regions of the T-cell receptor and thereby activate subsets of T cells that carry that particular V β region. During the acute phase of the disease, T cells from the peripheral blood show an expansion of V β 2 and V β 8 T-cell receptor families, suggesting stimulation by staphylococcus- or streptococcus-derived superantigens. These superantigens *in vivo* can bridge MHC class I- and II-expressing endothelial cells with CD8+ and CD4+ T cells. However, levels of antibodies to staphylococcal and streptococcal superantigens have not been found to differ between patients with Kawasaki disease and healthy control subjects. As mentioned earlier, intravenous immunoglobulin is an effective treatment in the acute phase to reduce the occurrence of coronary artery aneurysms. The efficacy of intravenous immunoglobulin might give a clue to the immunopathogenesis of Kawasaki disease, but no consistent explanations have been given. Thus, at present, Kawasaki disease is considered to arise from an aberrant immune response to as yet undefined microorganisms in a genetically susceptible host.⁴⁶

IMMUNOPATHOGENESIS OF LARGE-VESSEL VASCULITIDES

In contrast to the necrotizing vasculitides affecting the small and medium-sized vessels, the large-vessel vasculitides are not dominated by polymorphonuclear cell infiltration but show a cellular immune response with infiltration of monocytes/macrophages and T cells. The two major diseases in this group are giant cell arteritis, also designated as *temporal arteritis*, and Takayasu arteritis.

Giant cell arteritis

Giant cell arteritis (GCA) is defined by the 2012 CHCC as “arteritis, often granulomatous, usually affecting the aorta and/or its major branches, with a predilection for the branches of the carotid and vertebral arteries; often involves the temporal artery; onset usually in patients older than 50; often associated with polymyalgia rheumatica.”²

GCA is characterized histopathologically by mononuclear infiltrates in all layers of the arterial wall in conjunction with activated T cells. Macrophages and T cells are present in granuloma formation, and multinucleated giant cells are localized close to the fragmented internal elastic lamina. Proliferation of the intima results in occlusive vasculopathy.

Insight into the immunopathogenesis of GCA stems mainly from the pioneering work of Weyand and Goronzy.^{47,48} These researchers attributed an initiating and central role to dendritic cells in the immunopathogenesis of GCA. Immature dendritic cells, lacking the costimulatory molecules CD80 and CD86, are present in the adventitia of arteries and, due to lack of costimulation, tolerize T cells that recognize (auto)antigens presented by these dendritic cells localized in the adventitial area. Immature dendritic cells can be activated *in vitro* and *in vivo* by stimulants such as lipopolysaccharide, which results in, among others, the expression of costimulatory molecules (CD80/86) and the capacity to activate T cells. Whereas dendritic cells in the adventitia of arteries from healthy controls are immature, temporal arteries from patients with polymyalgia rheumatica without inflammatory changes display mature dendritic cells in their adventitia. These dendritic cells, in contrast to adventitial dendritic cells from control

subjects, are able to activate T cells derived from GCA lesions, as shown in experiments in mice with severe combined immunodeficiency in which the respective temporal arteries were implanted and T cells adoptively transferred.⁴⁹ Thus *in situ* maturation of dendritic cells in the adventitia seems an initial event in the immunopathogenesis of GCA. How these dendritic cells get activated is presently unknown. The second element is constituted by CD4+ T cells that interact with these mature dendritic cells. The crucial question of what these T cells recognize has not been answered. Autoantigens and various microorganisms—in particular parvovirus, varicella-zoster virus, and *Chlamydia*—have been suggested but not substantiated. Mature dendritic cells in the adventitial layer of the temporal artery produce the chemokines CCL19 and CCL21 and express receptors for these chemokines as well. This causes the dendritic cells to remain *in situ* instead of migrating into regional lymph nodes and allows the local interaction with CD4+ T cells.⁴⁹

Activation of T cells leads to a Th1- and Th17-type response via dendritic cell-derived IL-18, with massive production of interferon- γ (IFN- γ) and IL-17, followed by the generation of granulomas that mainly localize in the media. Here, macrophages are activated by IFN- γ and produce reactive oxygen species, nitric oxide via upregulation of iNOS, and metalloproteinases. IFN- γ also induces the generation of multinucleated giant cells that contribute to the production of PDGF and, in particular, VEGF. Th1 and Th17 immunity seems responsible for the early phase and Th1 immunity for the more chronic smoldering inflammation.⁵⁰ The response to injury of the arterial vessel wall determines the level of occlusion of affected arteries and the occurrence of ischemic lesions. VEGF production results in neovascularization in the media and intima, which allows further proliferation of myofibroblasts, a process that is also dependent on PDGF production (Fig. e154.3).

Besides this cellular immune response that results in arteritis of the extracranial branches of the aorta, a systemic inflammatory response is characteristic of GCA as well. This inflammatory response is comparable to that occurring in polymyalgia rheumatica in which large-vessel arteritis is, as far as we know, lacking. It is initiated by proinflammatory cytokines, in particular IL-1 and IL-6, and is apparent in the production by the liver of acute-phase proteins such as C-reactive protein. There is evidence that these proinflammatory cytokines are mainly produced by circulating monocytes, but how these cells are stimulated in GCA and polymyalgia rheumatica is presently unknown.

Takayasu arteritis

Takayasu arteritis is defined by the 2012 CHCC as “arteritis, often granulomatous, affecting the aorta and its major branches. Onset usually in patients younger than 50.”² This disease, which is in several ways comparable to GCA, occurs far more frequently in people from Japan, Southeast Asia, India, and Mexico than in whites, in whom GCA predominates. These racial differences suggest genetic factors, but specific genes have not been identified beyond weak human leukocyte antigen associations. Immunohistopathologic analysis of the infiltrates in acute phases of the disease points toward a cellular immune response with infiltration of both Th1 and Th17 cells, natural killer cells, and CD8+ cytotoxic T cells. Th1 cells induce activation of macrophages and the formation of giant cells. Th17 cells contribute to the inflammatory lesions by activating neutrophils. Natural killer cells and $\gamma\delta$ T cells interact via their NKG2D receptor with MICA antigens on vascular smooth muscle cells, which results in cytotoxicity via their production of perforin.⁵¹ Further analysis shows a restricted use of T-cell receptor $\alpha\beta$ genes in lesional tissue. This may suggest that a specific antigen or a superantigen is operative in this disease. The nature of this (super) antigen, however, has not been identified.

Fig. e154.3 (a) Activation and trapping of dendritic cells in the arterial adventitia generate the conditions required for the recruitment and stimulation of antigen-specific T cells. CD4⁺ T cells that enter the microenvironment of the arterial wall interact with dendritic cells and begin secreting cytokines. Interferon- γ is a critical cytokine that regulates the differentiation and function of macrophages. The functional commitment of the macrophages in the vascular infiltrates is closely linked to their location in the arterial wall. Macrophages in the adventitial layer supply the inflammatory cytokines interleukin-1 and interleukin-6. Macrophages in the media secrete metalloproteinases and play a critical part in oxidative injury through the production of reactive oxygen intermediates. (b) Three aspects of oxidative damage in the media are shown. Protein nitration occurs in endothelial cells lining neocapillaries. Toxic aldehydes are formed in the process of lipid peroxidation, and smooth muscle cells undergo apoptosis. In parallel, reactive oxygen intermediates also trigger cellular activation, as exemplified by the induction of aldose reductase. (c and d) The response of the artery to injury is shown. Arteritis does not necessarily result in luminal stenosis and may proceed without compromising blood flow (c). In patients with ample production of platelet-derived growth factor and vascular endothelial growth factor, rapid and exuberant intimal hyperplasia ensues, causing lumen-occlusive arteritis (d). Accordingly, the clinical presentation of arteritis may or may not include ischemic complications. (Reproduced with permission from Weyand CM, Goronzy JJ. Polyarteritis nodosa and Cogan syndrome

■ ELEANA NTATSAKI ■ RICHARD WATTS ■ DAVID G.I. SCOTT

- Polyarteritis nodosa is a necrotizing arteritis of medium or small arteries without glomerulonephritis or vasculitis in arterioles, capillaries, or venules and is not associated with anti-neutrophil cytoplasmic autoantibodies. It is a rare disease but more common in areas endemic for hepatitis B virus infection. Patients typically have systemic symptoms, and organs involved include the kidneys, skin, joints, muscles, nerves, and gastrointestinal tract. Testicular involvement, though characteristic, is less common, as is cardiac involvement. The lungs are usually spared.
- Polyarteritis nodosa is a monophasic self-limited disease that tends to not recur once remission is induced. It is treated with corticosteroids, but strategy options vary according to the underlying etiology and disease severity. Therapeutic options include cyclophosphamide, plasma exchange for severe cases, and antiviral medications for patients with hepatitis B virus-associated polyarteritis nodosa.
- Cogan syndrome is a rare, chronic inflammatory disease of unknown etiology that predominantly affects the eye and inner ear and is reported mostly in young white adults. It can be associated with vasculitis and aortitis. The hallmarks of Cogan syndrome are interstitial keratitis and recurrent Ménière-like episodes that can result in deafness. Infections and inflammatory conditions that affect the ears and eyes need to be considered in the differential diagnosis.
- Cogan syndrome is treated with corticosteroids for acute flares and recurrences of ocular or auditory inflammation. Other immunosuppressive drugs such as cyclophosphamide, azathioprine, methotrexate, and cyclosporine can be used when corticosteroid treatment fails. The prognosis varies according to disease activity. Ocular outcomes are good, but deafness is the most common long-term consequence.

INTRODUCTION

The systemic vasculitides are a heterogeneous group of multisystem disorders characterized by inflammation and necrosis of small and medium-sized blood vessels. The first cases of vasculitis were reported in the mid-1800s with the description of peri(poly)arteritis nodosa (PAN), a term later used collectively to describe a whole spectrum of vasculitic diseases, particularly until the mid-20th century.¹ The development during the last 30 years of different classification systems and the introduction of classification criteria have further broadened our understanding of these conditions. The American College of Rheumatology (ACR) classification criteria (1990),² however, did not recognize microscopic polyangiitis (MPA), in contrast to most other vasculitides, including PAN. The introduction of antineutrophil cytoplasmic antibodies (ANCA) in the late 1980s with their strong links to a group of vasculitides (sometimes called ANCA-associated vasculitis [AAV]) also helped develop our understanding of the potential for separating and classifying these diseases by recognizing that PAN is not associated with ANCA.

The Chapel Hill Consensus Conference in 1994 (CHCC 1994) defined the typical features of many of the vasculitides, including Wegener granulomatosis (WG), MPA, and Churg-Strauss syndrome (CSS) (also closely associated with ANCA).³ The CHCC 1994 used the term “classic (c)” PAN to help differentiate MPA from cPAN³ because we now recognize these diseases to be very different clinicopathologic conditions. MPA is usually restricted to relatively small blood vessels; it is strongly linked to ANCA and is much more common than PAN, which is a disease of mainly

medium-sized arteries that is rarely associated with ANCA and not infrequently linked to infection with hepatitis B virus (HBV). With evolving knowledge and understanding of the different vasculitides, a further Chapel Hill meeting was conducted in 2011 (published in 2012, the so-called CHCC 2012) to improve and develop definitions and classification of the different vasculitic diseases, as well as to introduce an updated nomenclature that includes WG, or granulomatosis with polyangiitis (GPA), and CSS, or eosinophilia with granulomatosis and polyangiitis (EGPA).⁴ They also included Cogan syndrome (CS) when associated with vasculitis (Cogan vasculitis) in recognition of the association of CS with vasculitis involving large and medium-sized arteries, sometimes similar to that seen with PAN. CHCC 2012 dropped the “c” from PAN as the ensuing years from 1994 had firmly established MPA as a separate disease entity.

The position of PAN and CS within the constellation of the vasculitides is described in Chapter 153.

POLYARTERITIS NODOSA

Definition

PAN is defined as “a necrotizing arteritis of medium or small arteries without glomerulonephritis or vasculitis in arterioles, capillaries, or venules; and not associated with anti-neutrophil cytoplasmic autoantibodies (ANCA).”⁴ In CHCC 2012, specifying that ANCA are not associated with PAN and the addition of a category for AAV reflect advances in knowledge gained about ANCA since CHCC 1994. Although the role of ANCA in the pathogenesis of vasculitis has not been fully elucidated, many studies have confirmed that ANCA are a reliable marker for a clinically and pathologically distinct category of small-vessel vasculitis and that they are typically absent in patients with PAN. Such a discriminator is useful because PAN and AAV can exhibit clinically and pathologically indistinguishable necrotizing arteritis of medium and small arteries.

Classification

Classification of the vasculitides remains confusing and controversial because of overlap in clinical expression of the different vasculitic syndromes. For practical purposes, classification generally reflects dominant vessel size and the presence or absence of ANCA. PAN, being predominantly a disease of medium vessels lacking association with ANCA, is placed in a group distinct from the AAVs (see Chapter 153).

In 1990 the ACR produced classification criteria for seven types of systemic vasculitis, including PAN but not MPA. The ACR classification criteria for PAN are presented in Table 155.1. The sensitivity of these criteria was 82.2% with a specificity of 86.9%.⁵ The criteria are not without problems; they were validated in patients known to have vasculitis but not in patients before the diagnosis of vasculitis or other systemic illnesses. Their reliability when used in patients in whom vasculitis is only suspected is poor. Furthermore, they did not consider ANCA.

The CHCC (1994 and 2012) provided definitions for PAN (and MPA). PAN was defined as a disease predominantly affecting medium or small arteries, whereas MPA was a condition affecting smaller microscopic vessels.^{3,4} A consequence of this distinction is that PAN has become very uncommon. The CHCCs provided only definitions and not formal classification criteria; the lack of criteria for MPA has resulted in the CHCC definitions being used to classify patients in epidemiology studies.

A further problem is that the criteria were developed for use in adults. A Paediatric Rheumatology European Society/European League Against Rheumatism working group published classification criteria for pediatric PAN in

TABLE 155.1
ACR 1990 criteria for the classification of polyarteritis nodosa*

Criterion	Definition
1. Weight loss >4 kg	Loss of 4 kg or more body weight since the illness began that is not due to dieting or other factors
2. Livedo reticularis	Mottled reticular pattern over the skin of portions of the extremities or torso
3. Testicular pain or tenderness	Pain or tenderness of the testicles not attributable to infection, trauma, or other causes
4. Myalgias, weakness, or polyneuropathy	Diffuse myalgias (excluding the shoulder and hip girdle)
5. Mononeuropathy or polyneuropathy	Development of mononeuropathies, multiple mononeuropathies, or polyneuropathy
6. Diastolic BP >90 mm Hg	Development of hypertension with a diastolic BP >90 mm Hg
7. Increased BUN or creatinine	Increase in BUN >40 mg/dL (14.3 mmol/L) or creatinine >1.5 mg/dL (132 mmol/L) not attributable to dehydration or obstruction
8. Hepatitis B virus	Presence of hepatitis B surface antigen or antibody in serum
9. Arteriographic abnormality	Arteriogram showing aneurysms or occlusions of the visceral arteries that is not due to arteriosclerosis, fibromuscular dysplasia, or other noninflammatory causes
10. Biopsy of small or medium-sized artery	Histologic changes showing the presence of a small or medium-sized artery containing PMN granulocytes or granulocytes and mononuclear leukocytes in the artery wall

*The traditional format. For classification purposes, a patient with vasculitis shall be said to have polyarteritis nodosa if at least 3 of these 10 criteria are present. The presence of any three or more criteria yields a sensitivity of 82.2% and a specificity of 86.6%. ACR, American College of Rheumatology; BP, blood pressure; BUN, blood urea nitrogen; PMN, polymorphonuclear leukocytes (granulocytes). Adopted from Lightfoot RW Jr, Michel BA, Bloch DA, et al. The American College of Rheumatology 1990 criteria for the classification of polyarteritis nodosa. *Arthritis Rheum* 1990;33:1088-93.

2010.⁶ These criteria do not include HBV infection because it is rarely a cause of PAN in children as a result of improved vaccination protocols.

The French study group recently developed criteria for PAN and introduced exclusion or negative criteria⁷ (Table 155.2). Of the original 10 ACR criteria, only 3 were maintained (presence of HBV antigen, arteriographic abnormalities, and neuropathy). The negative criteria were considered to not be features of PAN and, if present, to be indicative of another type of vasculitis. The sensitivity of these criteria was 70.6% with a specificity of 92.3%.

It is worth stressing that validated diagnostic criteria for PAN are still not available.

Epidemiology

PAN is uncommon. Estimates before the introduction of modern classification systems showed an annual incidence in a general population ranging from 9.0 to 77 per million.⁸ The highest figure was observed in a hepatitis B–endemic Alaskan Eskimo population.⁹ These figures included MPA, PAN, connective tissue disease–associated vasculitis, and EGPA (CSS). PAN, however, is much less common than previously reported because of the current, more strict CHCC definitions. In U.K. epidemiology studies, PAN is very rare and occurs much less frequently than MPA at a rate of probably less than 1 per million per year. In Kuwait the annual incidence was much higher at 16.4 per million.¹⁰ PAN occurs at all ages and is more common in men. The mean age at the onset of PAN is 51 years.¹¹

Environmental factors

The major environmental risk factor is HBV infection, which has been firmly associated with PAN for 40 years. In areas endemic for HBV infection, up to 95% of cases are associated with it. In France, falling HBV infection rates have correlated with a decrease in HBV-associated PAN.¹² In Alaska,

TABLE 155.2
The French Vasculitis Study Group minimal set of low-redundant predictive criteria for polyarteritis nodosa

Criterion	Polyarteritis nodosa association
HBV infection	Positive
ANCA positivity	Negative
Asthma	Negative
ENT signs	Negative
Cryoglobulin positivity	Negative
Glomerulonephritis	Negative
Arteriographic abnormalities	Positive
Mononeuropathy/polyneuropathy	Positive

ANCA, antineutrophil cytoplasmic antibody; HBV, hepatitis B virus; ENT, ear, nose, and throat. Data from Henegar C, Pagnoux C, Puechal X, et al. A paradigm of diagnostic criteria for polyarteritis nodosa: analysis of a series of 949 patients with vasculitides. *Arthritis Rheum* 2008;58:1528-38.

HBV-associated PAN has disappeared from the population following the introduction of a vaccination program. In this population, infection was associated with D genotype HBV.¹³ Other viruses such as human immunodeficiency virus (HIV), parvovirus B19, and hepatitis C virus (HCV) have also been associated with PAN.¹⁴

Clinical features

PAN has a spectrum of severity from mild, limited disease to progressive disease, which may be fatal. Virtually any organ may eventually be affected. Typically, patients experience the constitutional features of fever, malaise, weight loss, and diffuse aching, along with manifestations of multisystem involvement such as peripheral neuropathy and an asymmetric polyarthritis. Visceral involvement, such as the kidney or gut, may occur coincidentally with these features or may appear later. Table 155.3 describes the clinical findings in a large group of patients with PAN, including those with HBV-related disease.

Cutaneous lesions

Cutaneous lesions, including infarctions, ulcerations, livedo reticularis, subcutaneous nodules, and ischemic changes in the distal ends of digits (Fig. 155.1), occur in 25% to 60% of patients. The frequency of skin lesions in PAN is not different from that in MPA. Biopsy does not necessarily help distinguish MPA from PAN.¹⁵

Musculoskeletal features

Arthralgia or arthritis is present in as many as 60% of patients. Patients may also initially be seen with or early in the course of the disease have a polymyalgia rheumatica–like syndrome. An asymmetric, episodic, nondeforming polyarthritis involving the larger joints of the lower extremity may occur in up to 20% of cases, most commonly early in the disease.

Neurologic features

Peripheral neuropathy may occur in up to 85% of patients with PAN and might be the initial manifestation.¹¹ It is more common in patients with HBV-related PAN. The neuropathy affects the lower extremities somewhat more often than the upper extremities. Its onset is often very acute, with pain and paresthesias radiating in the distribution of a peripheral nerve, followed in hours by a motor deficit of the same peripheral nerve. This may progress asymmetrically to involve other peripheral nerves and produce mononeuritis multiplex or multiple mononeuropathy. With additional nerve damage, the final result may be a symmetric polyneuropathy involving all sensory modalities and motor functions. Less commonly, a slowly evolving distal sensory neuropathy or cranial nerve palsy may occur. Clinical manifestations suggestive of central nervous system (CNS) involvement are much less common than those of peripheral nerve involvement, but the two may appear together. CNS involvement includes headache, seizures, cranial nerve dysfunction, cerebral hemorrhage, and stroke.

Renal involvement

PAN is usually characterized by vascular nephropathy, without glomerulonephritis, in about 35% of patients.¹¹ Multiple renal infarcts, the consequence of vascular nephropathy, produce renal failure. Renal angiography

TABLE 155.3

Main clinical characteristics at diagnosis of 348 patients with PAN by HBV status

Characteristic	All patients (N = 348)	Non-HBV-related PAN (n = 225)	HBV-related PAN (n = 123)	P
No. of men/women (ratio)	220/128 (1.7)	137/88 (1.6)	83/40 (2.1)	
Age at diagnosis (yr, mean $\pm$ SD)	51.2 $\pm$ 17.3	50.9 $\pm$ 17.8	51.7 $\pm$ 16.4

§Pulmonary manifestations were nonspecific and caused by cardiac or renal insufficiency, or both.

BVAS, Birmingham Vasculitis Activity Score; FFS, Five-Factor Score; HBV, hepatitis B virus; PAN, polyarteritis nodosa; SD, standard deviation.

Adapted and modified from Pagnaux C, Serar R, Henegar C, et al. Clinical features and outcomes in 348 patients with polyarteritis nodosa: a systematic retrospective study of patients diagnosed between 1963 and 2005 and entered into the French Vasculitis Study Group Database. *Arthritis* 2010;62:616-26.

will frequently show several aneurysms and infarcts. Ureteral stenosis and perinephric hematomas (microaneurysm rupture) can occur. Hypertension develops as a result of renal artery or, less commonly, renal parenchymal involvement. Hypertension, usually mild, develops in 20% to 50% of patients and is particularly associated with HBV infection.¹¹

Gastrointestinal involvement

Abdominal pain occurs in up to 70% of patients and is more common in those with HBV-related disease.¹¹ Other features of gastrointestinal involvement include diarrhea, gut hemorrhage, and abnormal liver enzyme test results. Liver involvement is not common clinically, except if associated with

Fig. 155.1 Cutaneous lesion of polyarteritis nodosa.

Fig. 155.2 Histopathology of polyarteritis nodosa.

HBV infection. Gastrointestinal involvement is among the most serious features of PAN and is associated with a poor prognosis. Abdominal pain secondary to vasculitis may be the first manifestation of vasculitis and presents a particular challenge.

Cardiac involvement

Cardiac involvement in patients with PAN is common pathologically but is recognized less often clinically. Myocardial infarction, when it occurs, is generally silent and due to coronary arteritis. The use of cardiac magnetic resonance imaging (MRI) to evaluate for coronary arteritis has been suggested as a less invasive means of assessing the extent of myocardial damage.¹⁶ Cardiomegaly occurs in about 20% of patients. Congestive heart failure develops as a result of coronary insufficiency or severe hypertension (or both). Cardiomyopathy is predictive of increased mortality. Endocarditis is not observed in patients with PAN, and its occurrence should alert the clinician to an alternative diagnosis.

Orchitis

Testicular involvement is manifested as pain, but clinical involvement as indicated by swelling or induration occurs in approximately 20% of patients. Orchitis is one of the most characteristic features of cPAN¹¹ and is more common in polyarteritis complicated by gastrointestinal involvement and vasculitis associated with HBV infection. It is rarely the first manifestation of the disease, is generally unilateral, and is caused by ischemia of the testicular artery.

Other features

Pulmonary involvement is uncommon in PAN, so other causes should be considered, especially infection.¹¹ Diffuse involvement of skeletal muscle arteries may cause ischemic pain and intermittent claudication. Myalgias occur in about 50% of patients with polyarteritis, but generalized myopathy and increased creatine kinase concentrations are unusual. Venous thromboembolism is less common than in AAV and occurs in 2.8% of patients.¹⁷

Secondary polyarteritis nodosa

Vasculitis of medium-sized vessels mimicking polyarteritis may be a manifestation or complication of other diseases. This secondary vasculitis occurs in patients with rheumatoid arthritis, Sjögren syndrome, hairy cell leukemia, myelodysplastic syndrome, and other hematologic malignancies. Secondary vasculitis is histopathologically and clinically indistinguishable from the primary forms.

Viruses, including HIV, are particularly inclined to cause small-vessel vasculitis, whereas bacterial infections have been associated with inflammation of all sizes of blood vessels. The association of PAN with HBV infection is particularly strong. Patients with HBV-associated PAN have more severe disease than do those with non-HBV-associated PAN, with greater weight loss and more frequent peripheral nerve involvement, abdominal pain, gastrointestinal manifestations requiring surgery, specific cardiomyopathy, orchitis, hypertension, and elevated transaminase levels¹¹ (see Table 155.3). The evaluation of every patient with vasculitis should include HBV serology. PAN is usually manifested within the first 6 months of HBV infection. Hepatitis is rarely diagnosed before the onset of PAN, which can therefore be the first manifestation of HBV infection.

HCV is also associated with PAN.¹⁴ Among a cohort of 161 patients with HCV-related vasculitis studied by the French group, PAN was diagnosed in 31 patients chronically infected with HCV, with both the ACR and Chapel Hill criteria being fulfilled. When compared with HCV-associated mixed cryoglobulinemic vasculitis, HCV-related PAN was associated with more

severe and acute clinical findings, such as more frequent fever and weight loss, severe hypertension, involvement of the gastrointestinal tract, severe acute sensory-motor multifocal mononeuropathy, and kidney and liver microaneurysms. Patients with HCV-related PAN had a higher rate of clinical remission. The overall 5-year survival rate was 86% for the entire cohort, regardless of the type of vasculitis. Patients with skin involvement and PAN-type vasculitis had a better chance for a complete clinical response than did patients with renal involvement, which had the opposite association.¹⁴

Limited forms of polyarteritis

Isolated polyarteritis of the appendix, gallbladder, uterus, or testis is well recognized, though uncommon. Vasculitic peripheral neuropathy can occur without other systemic or constitutional symptoms. A cutaneous form of polyarteritis that affects predominantly the lower extremities is distinguished from systemic polyarteritis by its lack of visceral involvement and benign course.¹⁸ Although the chronic, relapsing, nonlethal nature of the condition has been stressed by some, other investigators have documented the refractory nature of chronic cutaneous vasculitis and the significant cumulative morbidity related to skin, muscle, joint, and nerve involvement and the effects of therapy.

Pathology

The pathology of polyarteritis consists of focal, necrotizing inflammatory lesions that extend through the wall of small and medium-sized arteries (Fig. 155.2). The inflammation is characterized by fibrinoid necrosis and pleomorphic cellular infiltration predominantly by macrophages and lymphocytes and variable numbers of neutrophils and eosinophils. A significant eosinophilic infiltrate favors the diagnosis of EGPA (CSS). The normal architecture of the vessel wall, including the elastic lamina, is disrupted. Thrombosis or aneurysmal dilation may be present at the site of the lesion. Healed areas of arteritis show proliferation of fibrous tissue and endothelial cells, which may lead to occlusion of the vessel. Lesions at all stages of progression and healing may be seen pathologically if sufficient tissue is available for study. The focal nature of the inflammation increases the risk for a false-negative biopsy result when the tissue sample is small. The finding of perivascular inflammation or intimal proliferation without fibrinoid necrosis of the arterial wall suggests, but does not confirm the diagnosis of polyarteritis. In autopsy studies of patients with PAN, inflammation is frequently found in the arcuate and interlobar arteries and arterioles of the kidney, along with evidence of infarction.

Investigations

The systemic inflammatory nature of PAN is reflected in the nonspecific findings of an increased erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) level, normochromic normocytic anemia, thrombocytosis, and diminished concentrations of serum albumin. Eosinophilia is not common and is generally associated with pulmonary involvement in EGPA (CSS).

ANCAs are generally considered to not be present in PAN. Rheumatoid factor, other than when present in rheumatoid arthritis, is frequently associated with cryoglobulins. Low-titer antinuclear antibodies are not seen often. Hypocomplementemia is more common in secondary polyarteritis.

Angiography is useful in patients with suspected polyarteritis, particularly if the symptoms and laboratory abnormalities do not direct the choice of biopsy. Angiography may be the diagnostic procedure of choice in patients with HBV-associated polyarteritis. The typical angiographic appearance

Fig. 155.3 Angiography of polyarteritis nodosa showing microaneurysms.

includes long segments of smooth arterial stenosis alternating with areas of normal or dilated artery, smooth tapered occlusions, thrombosis, and a lack of significant atherosclerosis (Fig. 155.3). The dilated segments include saccular and fusiform aneurysms, which strongly suggests PAN. The most frequently involved vessels are the renal, hepatic, and mesenteric vessels. When angiography is performed, it is important that all intraabdominal vessels be studied, including the celiac axis and the mesenteric, renal, and hepatic arteries. The angiographic appearance may regress after treatment. A number of uncommon conditions can mimic the visceral angiographic appearance of vasculitis, including bacterial endocarditis, atrial myxoma, drug abuse, pancreatitis, abdominal malignancy, and disorders of connective tissue.

Although most reported data are derived from conventional contrast-enhanced angiography, magnetic resonance angiography (MRA) can be used as an alternative to classic angiography. A small study looking at imaging of renal involvement in PAN suggested that in the absence of microaneurysms, differentiation between PAN and pyelonephritis with computed tomography (CT) and MRI is difficult. The authors concluded that plain dynamic abdominal imaging, though diagnostically helpful, is often inconclusive and that angiography is therefore required for a definite diagnosis.¹⁹ MRA and contrast-enhanced MRI can also be used to assess for coronary arteritis and myocardial dysfunction and may reveal coronary ectatic disease in patients with MPA and PAN.¹⁶

Muscle biopsy specimens are positive in around 50% of patients with PAN who have muscle pain or claudication. The yield of muscle biopsy is lower in asymptomatic cases.

Assessment of disease activity and damage

Modern therapy for the systemic vasculitides has dramatically altered the prognosis from an acute fulminating life-threatening condition to a chronic disease, with considerable morbidity arising from either disease activity or therapy. Several systems have been developed to assess disease activity and damage, including the Birmingham Vasculitis Activity Score (BVAS), the Groningen Index, and the Vasculitis Activity Index. The BVAS is the most widely applicable to different types of necrotizing vasculitis and has been systematically validated.²⁰ The BVAS is a comprehensive scoring system that includes nine organ systems. Clinical features that are attributable to active vasculitis and that have occurred anew and been present within the previous 4 weeks are recorded. Organ involvement associated with a worse prognosis is given greater weighting. The BVAS has also been used to develop definitions of remission and relapse, which are now being used in multicenter trials.

Vasculitis results in organ damage from either the disease itself or therapy. Damage is defined as an irreversible process that is the result of scars and

not due to acute inflammation or persistent disease activity. The Vasculitis Damage Index (VDI) is also an organ-based system and is scored after 3 months. The VDI is comprehensive, permits assessment of the accumulation of damage with time, and has been validated²¹; however there are concerns that it may not adequately determine the full spectrum of damage experienced by patients with vasculitis of small- and medium-sized vessels. An ongoing international initiative (OMERACT Vasculitis Working group) is aiming to create an evidence-based unified approach to assessment of disease for the primary systemic vasculitides by revising and improving damage assessment tools.²²

The final component of patient assessment is quality of life. The Medical Outcomes Study Short-Form 36-Item Health Survey (SF-36) has been validated for use in patients to assess vasculitis. An emerging patient-reported outcome is health-related quality of life, which is the component of a patient's quality of life that is thought to be attributable to health status rather than education or socioeconomic status.

Differential diagnosis

To establish a diagnosis of PAN, other causes of systemic illness (infection such as endocarditis) and pseudo-vasculitic syndromes such as cholesterol emboli, atrial myxoma, and antiphospholipid syndrome should be excluded, as well as other types of vasculitis that can also involve medium-sized arteries, including the AAVs. Secondary PAN and limited PAN forms should also be considered in the differential diagnosis.

Management

The natural history of untreated PAN is a rapidly progressive, usually fatal disease. The introduction of corticosteroids resulted in an improvement in the survival rate of patients with PAN to 50% at 5 years.²³ A number of randomized controlled trials have been performed, but they included patients with CSS and preceded introduction of the CHCC definitions for PAN and MPA.

The French group analyzed the results from four of their prospective trials, including patients with PAN, that were carried out between 1980 and 1993²⁴:

- Corticosteroids and plasma exchange versus corticosteroids and plasma exchange plus oral cyclophosphamide (CYC) in patients with PAN, CSS, or MPA
- Corticosteroids alone versus corticosteroids and plasma exchange in patients with PAN (without HBV), MPA, or CSS
- Corticosteroids and pulse CYC versus corticosteroids, pulsed CYC, and plasma exchange in patients with poor-prognosis PAN (without HBV), CSS, and MPA; good-prognosis patients received corticosteroids and either pulsed or continuous CYC
- Corticosteroids and antiviral therapy in patients with PAN associated with HBV

The 278 patients were reclassified according to the current definitions of PAN, MPA, and CSS. Overall survival was the same in the 215 patients who received CYC plus corticosteroids or corticosteroids alone. Stratification for disease severity suggested that patients with more severe disease had prolonged survival when treated with CYC. In this analysis, 15 of the 22 patients who died of severe vasculitis had not received corticosteroids. CYC did not, however, appear to reduce the relapse rate. The authors concluded that CYC should be used only in patients with severe disease at initial evaluation.

A recent prospective, multicenter trial by the same group recruited 124 patients with newly diagnosed PAN or MPA from 1993 to 2005 and assessed the efficacy of systemic corticosteroids alone as first-line treatment of PAN and MPA without poor-prognosis factors (as defined by the Five-Factors Score [FFS]). It also compared the efficacy and safety of azathioprine versus pulsed CYC as adjunctive immunosuppressive therapy for patients experiencing treatment failure or relapse. At the time of treatment failure or relapse of disease, patients were randomized to receive 6 months of therapy with oral azathioprine or six pulses of CYC. The overall 5-year survival rate was good (92%), but first-line corticosteroid treatment was able to achieve and maintain remission in only about half the patients, and 40% required additional immunosuppressive therapy. Azathioprine or pulsed CYC was fairly effective in treating corticosteroid-resistant disease or major relapses. Disease-free survival was found to be significantly lower in patients with MPA than in those with PAN.²⁵

The best treatment strategy for patients with systemic vasculitis associated with viral infection should take into account the etiology of the disease and be adapted to the pathogenesis.²⁶ The combination of plasma

exchange and antiviral treatment has been shown to be effective in HBV-associated PAN. Antiviral drugs that have been used with benefit include vidarabine, interferon alfa, and lamivudine,²⁶ the latter giving the best results. Lamivudine 100 mg/day is used with plasma exchange after a few days of steroids treatment (the dose should be reduced in patients with renal impairment), and this regimen is associated with 90% recovery and 60% seroconversion to anti-HBe. The French group used plasma exchange four times per week for 3 weeks, three times per week for 2 to 3 weeks, and then progressive lengthening between sessions. The response clinically can be very rapid, with recovery within 3 weeks. Plasma exchange should be stopped if anti-hepatitis B antibodies are detected (to avoid clearance of them as well).

Rituximab, a chimeric monoclonal antibody, induces selective depletion of B lymphocytes by targeting the CD20 surface antigen. Although good evidence supports the use of rituximab both for induction of remission and for maintenance therapy, especially with refractory AAV, not much evidence other than isolated case reports supports its use for PAN.²⁷

Similarly, there is a lack of robust scientific evidence to guide treatment of the limited variant “cutaneous PAN.” Most experts recommend less aggressive therapy with nonsteroidal antiinflammatory drugs or with other agents such as colchicine or dapsone.²⁸

Prognosis

PAN can be considered to be a monophasic self-limited disease that tends to not recur once remission is induced. In a series of patients with HBV-associated PAN, around 6% relapsed and the relapse rate is thought to be similar to that in those with non-HBV-associated PAN.¹²

The FFS at initial encounter is a useful guide to prognosis. The following parameters are assessed: proteinuria greater than 1 g/day, creatinine level higher than 140 $\mu\text{mol/L}$, cardiomyopathy, gastrointestinal symptoms, and CNS involvement. An FFS of greater than 2 in patients with PAN is associated with greatly increased mortality. The major cause of death in HBV-related PAN is gastrointestinal tract involvement.¹² A large systematic retrospective study of 348 patients with PAN between 1963 and 2005 showed that survival rates differed significantly between patients with an FFS of 0 and those with an FFS of 1 or 2 and between patients with HBV-related PAN and patients with non-HBV-related PAN. Patients in whom PAN was diagnosed after 1995 had better outcomes. Clinical parameters associated with increased risk for death in multivariate analysis were age older than 65 years, recent-onset hypertension, or gastrointestinal manifestations requiring surgery at diagnosis. A higher risk for relapse was associated with non-HBV-related PAN and the presence of skin manifestations, especially nodules.¹¹

COGAN SYNDROME

Definition

CS is characterized by ocular inflammatory lesions, including interstitial keratitis (IK), uveitis, and episcleritis, and inner ear disease, including sensorineural hearing loss and vestibular dysfunction. Vasculitic manifestations may include arteritis (affecting small, medium, or large arteries), aortitis, aortic aneurysms, and aortic and mitral valvulitis.⁴ The primary ocular vascular target for inflammation in CS is small vessels in the vascularized layers of the anterior part of the globe, specifically, from outer to inner, the conjunctiva (conjunctivitis), episclera (episcleritis), sclera (scleritis), and uvea (uveitis). Inflamed small blood vessels invade the adjacent normally avascular corneal stroma and cause the very distinctive IK of CS.

Classification

The vasculitis occurring in patients with CS is classified as a variable-vessel vasculitis. The diagnosis of CS is based on the characteristic involvement of both the eye and the inner ear in a young adult. As in PAN, no validated diagnostic criteria have been established.

CS was first described as a separate medical entity in 1945 by David Cogan, an ophthalmologist from the Massachusetts Eye and Ear Infirmary in Boston. He described four patients with a combination of nonsyphilitic IK and vestibuloauditory symptoms that resembled Ménière disease.²⁹ In differentiating these cases from the IK and hearing loss that occur in congenital and tertiary syphilis, Cogan emphasized that both the results of clinical examination and the course of the disease and its sequelae were distinguishable. The onset of eye disease in CS is gradual, and the cornea is not affected much, even after months of follow-up. On the other hand,

syphilitic disease begins abruptly, peaks within a fortnight, and then gradually improves. In syphilis, deafness occurs with a significant delay of months or years and usually in patients with severe IK.

Typical and atypical Cogan syndrome

In 1980, Haynes and colleagues³⁰ divided CS into “typical” and “atypical” after reviewing 13 new cases of CS seen at the National Institutes of Health. The “atypical” forms were characterized by more serious inflammatory disease of the eye, such as scleritis and posterior uveitis, and a higher degree of association with systemic vasculitis. In 2004 a French case series³¹ describing 17 typical and 15 atypical cases of CS concluded that caution should be exercised before endorsing a diagnosis of atypical CS because it may share common manifestations with other systemic diseases such as sarcoidosis, rheumatoid arthritis, juvenile idiopathic arthritis, Sjögren syndrome, inflammatory bowel disease, and AAVs. The biggest case series to date, from Mayo Clinic in 2006, also concluded that division of CS into two forms was no longer relevant,³² mainly because an increasing number of patients with typical CS and vasculitis had been described in the literature, thus making this distinction redundant.

Epidemiology

CS is predominantly a disease of white adults with the peak incidence occurring in the 20- to 30-year-old age group. CS is not associated with any gender or geographic predominance. Although around 250 patients with CS have been reported in the literature, there is considerable publication overlap, with some cases being reported more than once. It is also likely that many cases remain unrecognized or labeled inaccurately as “idiopathic” autoimmune ear disease, hearing loss, or keratitis.³³ Therefore, the actual incidence and prevalence are unknown, but overall, CS is considered a rare disease.

Environmental factors

The etiology of CS is unknown but it is thought to result from an environmental trigger interacting with a genetically predisposed host. Infection may act as a precipitator.³⁴ This is supported by observations that 25% to 33% of patients with CS have an antecedent flulike illness.^{30,32} Despite several attempts to link CS with a variety of infectious agents, including *Borrelia burgdorferi* and various *Chlamydia* species, there have been no conclusive results showing any significant associations. Furthermore, antibiotic treatment has never proved effective.³¹

A few patients exhibit reactivity against inner ear antigens that have sequence homology with Ro/SSA autoantigen and a core protein antigen of reovirus type III.³⁵ Based on animal studies in which passive transfer of the autoantibodies reproduced the features of CS, it is speculated that infection with reovirus type III may be a trigger for CS through the mechanism of molecular mimicry.

Cigarette smoking is considered an additional trigger.³² Among the 60 patients seen in the Mayo Clinic between 1940 and 2002, 31 (52%) were smokers, a rate approximately twice that in the general population.

Clinical features

The combination of ocular and vestibular symptoms in a young adult should raise suspicion for CS. Either of these organs is almost equally likely to be the cause of the initial symptoms.

Nonspecific systemic symptoms such as fever, weight loss, and fatigue may occur before any ocular or audiovestibular manifestations in less than 5% of patients.^{30,32} However, to establish a diagnosis of CS it is necessary to have either eye or inner ear disease manifestations, which are rare in PAN. Other systemic features such as lymphadenopathy, organomegaly, serositis, musculoskeletal symptoms, and urticaria have also been described.³¹⁻³³

Ocular

The predominant ocular feature is IK, which is typically manifested as a painful red eye, photophobia, and blurred vision. Diplopia, tearing, visual field defects, and a sensation of a foreign body in the eye also occur as initial findings.³⁰

Because the ocular manifestations may be intermittent and fleeting, close monitoring with repetitive eye examinations is necessary to monitor for ocular inflammatory disease, particularly IK.³⁶ Slit-lamp examination will demonstrate a patchy, deep, granular corneal infiltrate in most cases (Fig. 155.4). Other ocular manifestations include conjunctivitis, iridocyclitis, scleritis/episcleritis, corneal ulceration, or more rare pathology such as vitritis, choroiditis and subretinal neovascular membrane, pars planitis, orbital pseudotumor, and cotton-wool spots. Retinal vasculitis can also occur

and is a serious complication that may lead to visual impairment; it thus requires urgent ophthalmologic intervention and aggressive treatment.

Vestibuloauditory

Vestibuloauditory dysfunction in CS is typically manifested as sudden unilateral involvement, but gradually progressive sensorineural hearing loss. Vestibular features include sudden-onset vertigo, nausea, vomiting, ataxia, and tinnitus.^{30,31} These symptoms may mimic attacks caused by Ménière disease with or without hearing loss and can also cause nystagmus and oscillopsia (the perception of objects jiggling backward and forward following abrupt turning of the head from side to side).

Fig. 155.4 Slit-lamp findings from a patient with Cogan syndrome and interstitial keratitis. A subtle stromal infiltrate (arrow) typical of early interstitial keratitis is demonstrated in the narrow band of light. (Reproduced with permission from McCallum RM, St. Clair EW, Haynes BF. Cogan's syndrome. In: Hoffman GS, Weyand CM, editors. *Inflammatory diseases of blood vessels*. New York: Marcel Dekker; 2002, p. 491-509.)

Recurrent episodes of inner ear disease can lead to cochlear hydrops and also to profound hearing loss, which occurs suddenly and affects both ears in 75% of patients.^{30,32} The resultant downward fluctuation of hearing related to cochlear hydrops can be secondary to changes in cochlear pressure rather than the inflammatory process alone.³⁷

Audiometry testing will typically show sensorineural hearing loss, predominantly affecting the low and high range of frequencies, and sometimes poor speech discrimination.

Vasculitis

Vasculitis occurs in approximately 15% to 20% of patients with CS.³³ CS-related vasculitis may affect any size of vessel, but it most commonly causes large-vessel vasculitis resembling Takayasu arteritis, with the typical histology characterized by infiltration of the walls with polymorphonuclear cells, mononuclear cells, and multinucleated giant cells; intimal proliferation; fibrinoid necrosis; and disruption of the elastic lamina.³⁸ Symptoms, including upper or lower limb claudication (or both) or renal artery stenosis may occur in patients with CS and mimic Takayasu-like large-vessel vasculitis.

Aortitis occurs in 10% of patients^{30,31} and can develop within weeks to years of the onset of CS. Proximal aorta involvement and aortic valve regurgitation are not uncommon. Thoracic and abdominal aortic aneurysms have also been described.³¹ Angiography shows occlusive disease of the major branches of the aorta in different levels³⁹ (Fig. 155.5). Small- and medium-vessel vasculitis similar to PAN has also been described with renal, gastrointestinal, musculoskeletal, and even neurologic manifestations. Coronary arteritis has likewise been reported.³⁹

Other systemic features

Nonspecific systemic symptoms often develop in patients with CS. Neurologic involvement is uncommon but may be manifested in the CNS as meningitis, encephalitis, psychosis, and seizures, as well as peripheral nerve involvement such as mononeuritis multiplex and cranial neuropathy. Musculoskeletal symptoms include nonspecific myalgia and arthralgia.³³

Associations with other disease

Other systemic diseases such as Crohn disease,³⁰ ulcerative colitis, sarcoidosis, hypothyroidism, and interstitial nephritis have occurred in association with CS.

Assessment of disease activity and investigations

Investigation is aimed at establishing the diagnosis and assessing the severity of organ involvement.

Blood and cerebrospinal fluid

Similar to PAN, the inflammatory nature of CS is reflected in the increase in CRP and ESR and the presence of leukocytosis. Hematologic examination may reveal anemia and leukocytosis with relative lymphopenia. In the context of suspected systemic vasculitis, in addition to routine hematologic and biochemical tests, urinalysis should be performed to look for proteinuria, hematuria, and red cell casts.

Serologic investigations, including ANCA, antinuclear antibodies, rheumatoid factor, anticardiolipin antibodies, complement, and cryoglobulins, are typically negative in CS but should be checked to exclude other systemic

Fig. 155.5 Large-vessel vasculitis in Cogan syndrome. (a) Stenotic lesion of the left subclavian artery (arrow). (b) Stenotic lesions in the left anterior descending coronary artery (arrows) with poststenotic dilatation. (c) Stenotic lesions in the right innominate artery (left arrow) and the left subclavian artery (right arrow). (d) Multiple lesions in the single right and duplicated left renal arteries (arrows). (Reproduced with permission from Allen NB, Cox CC, Cobo M, et al. Use of immunosuppressive agents in the treatment of severe ocular and vascular manifestations of Cogan's syndrome. *Am J Med* 1990;88:296-301.)

disease. Virologic and microbiologic investigations to exclude syphilis and Lyme disease or hepatitis should also be considered.

Inner ear autoantibodies such as anti-hsp70 and anti-68 kDa are often used as a marker of autoimmune sensorineural hearing loss; however, they have no specificity for CS.^{34,40} There are autoantibodies more specific to CS that target a peptide antigen (called Cogan peptide) that shares sequence homology with CD148 and connexin 26, which are expressed on inner ear endothelial cells. These autoantibodies have been found in sera from patients with CS and are able to transfer the disease to animals in laboratory conditions. Although their presence confirms the autoimmune nature of CS, they are not routinely used in clinical practice.³⁴

Cerebrospinal fluid examination might reveal pleocytosis and increased protein and gamma-globulin.³⁰

Assessment of organ involvement

Ocular

Slit-lamp examination is used to evaluate and observe for the presence of IK, which is found in 70% of patients (see Fig 155.4). The typical earliest findings are giant corneal infiltrates 0.5 to 1 mm in diameter. A thorough ophthalmologic examination should also assess for the presence of scleritis or episcleritis, iridocyclitis, conjunctivitis, and any evidence of anterior or posterior ocular inflammation. Ophthalmic photography may be used for follow-up of any affected segments. Fluorescent angiography may help in assessing for retinal vasculitis or retinochoroiditis.

Vestibuloauditory

Otologic examination with an audiogram is necessary to document any hearing loss (occurs in 95% of patients). Audiometry will typically reveal relative sparing of the middle range, a pattern similar to that of Ménière syndrome. The presence of oscillopsia or nystagmus should be evaluated. Brainstem evoked potentials are abnormal in patients with cochlear damage. Caloric responses are abnormal with vestibular injury.

Cardiovascular

Symptoms of aortitis range from an asymptomatic murmur to exertional dyspnea, chest pain, and congestive heart failure with severe aortic regurgitation.^{39,41} A thorough physical cardiovascular examination should be performed in all patients with CS (including bilateral blood pressure assessment to identify any discrepancy suggestive of large-vessel arteritis). In the presence of evidence suggestive of myocardial infarction,²⁹ pericarditis,³⁹ left ventricular hypertrophy, or arrhythmias, further cardiovascular investigations such as electrocardiography, echocardiography, and cardiac angiography should be considered.

Echocardiography may show signs of aortic regurgitation such as “fluttering” of the anterior mitral valve leaflet, thickening of the valve cusps,⁴² paradoxical movement of the ascending aorta during systole,⁴¹ and left ventricular enlargement.^{41,42} Cardiac catheterization helps in the evaluation of hemodynamics^{38,41,43} and in the diagnosis of aortic valvular disease. Coronary angiography may reveal ostial coronary stenosis^{39,41} and distal coronary arteritis, whereas visceral angiography can demonstrate the typical lesions of Takayasu-like or polyarteritis-like vasculitis^{38,41,42} (see Fig 155.5).

Positron emission tomography is an emerging modality for the diagnostic workup of other types of large-vessel involvement such as Takayasu vasculitis. However, its role remains to be determined in CS-related large-vessel vasculitis.^{33,44}

Neurologic

MRI is typically useful in excluding the presence of an acoustic neuroma, other brain stem lesions, or a tumor in the cerebellopontine angle. In some patients with CS, brain MRI and CT have shown soft tissue and calcified obliteration of vestibular and cochlear structures. With gadolinium-enhanced MRI, disruption of the blood-labyrinthine barrier may be seen as enhancement of the vestibular and cochlear structures.⁴⁵

Differential diagnosis

CS should be considered in patients with ocular inflammation and evidence of audiovestibular dysfunction. The differential diagnosis of CS is broad and depends on the clinical findings, but CS should be distinguished mainly from other types of vasculitis that may cause scleritis or uveitis (i.e., GPA, PAN, Behçet disease). Furthermore, infectious causes of IK should also be considered and excluded with serologic testing and cultures. Several disorders produce ocular inflammation and vestibuloauditory dysfunction similar to CS. Examples include syphilis, Lyme disease, Vogt-Koyanagi-Harada syndrome, toxic exposures, and Ménière disease. Finally, nonocclusive, nonvasculitic vasculopathy should also be considered.

TABLE 155.4

Treatment of Cogan syndrome

Disease manifestations	Recommended treatment
Ocular	
Interstitial keratitis	Topical ocular corticosteroids and mydriatics (atropine)
Iridocyclitis	Low-potency topical corticosteroids such as 1% prednisolone acetate (3-7 days)
Anterior uveitis	Systemic corticosteroids (only in the case of failure of topical therapy)
Suspected chlamydial infection	Treatment with a tetracycline antibiotic (doxycycline) (200 mg daily for 2-3 wk)
Posterior-segment ocular inflammation	Systemic steroids DMARDs as steroid-sparing agents
Audiovestibular	
Acute vestibular symptoms	Diuretics, antihistamines, bed rest
Chronic vestibular symptoms	Vestibular exercises
Hearing loss	
Hearing loss	Corticosteroids: prednisolone 1 mg/kg daily (up to 60 mg) for 2 wk and then taper. Duration of initial treatment, 4-6 mo. Consider immunosuppressant therapy with steroid-sparing agents
Severe hearing loss unresponsive to medical treatment	Cochlear implant
Systemic vasculitis	
Cogan syndrome with large-vessel vasculitis	Corticosteroids and cyclosporine or cyclophosphamide
Cogan syndrome with medium-vessel vasculitis	Corticosteroids and cyclophosphamide as per treatment of polyarteritis nodosa

DMARD, disease-modifying antirheumatic drug.

Management

Patients with CS may go to different specialists, depending on their symptoms, and may initially be managed in an eye or an ear, nose, and throat clinic. However, these patients are best managed by a multidisciplinary team that includes ophthalmologists, otolaryngologists, audiologists, and rheumatologists. A summary of treatment options is outlined in Table 155.4.

Main principles

- The mainstay treatment of acute flares and recurrences if ocular and auditory inflammation is present is glucocorticoids.
- Keratitis and anterior uveitis usually respond to topical steroids. However, posterior scleritis and retinitis may require oral glucocorticoids.
- Audiovestibular disease requires high-dose oral steroids (1 to 2 mg/kg/day of prednisolone).
- Resistant disease or systemic disease with vasculitis requires immunosuppression.

Ocular disease

IK and iridocyclitis/anterior uveitis are treated with topical ocular corticosteroids and mydriatics to control inflammation and prevent synechiae. Low-potency topical corticosteroids such as 1% prednisolone acetate are often adequate for treating IK, and the symptoms tend to improve within a week.³⁰ Systemic corticosteroids are not generally indicated but may be used in the rare case of failure of topical therapy.^{30,46}

In nonresponding patients, chlamydial infection should be considered as a possible cause of the inflammation, and a trial of treatment with a tetracycline antibiotic such as doxycycline should be considered (200 mg daily for 2 to 3 weeks).⁴⁶ Conjunctivitis, scleritis, and episcleritis can also be treated with topical corticosteroids. Nodular scleritis warrants more aggressive therapy with systemic corticosteroids or other potent immunosuppressive drugs. Episcleritis and scleritis can be managed with topical or systemic nonsteroidal antiinflammatory therapy.

Posterior-segment ocular inflammation that is progressive or persistent or interferes with vision requires systemic corticosteroid therapy with prednisolone 1 mg/kg.^{30,37} Progression of posterior ocular inflammation despite systemic corticosteroids or failure to respond after 2 to 3 weeks of high-dose steroids should prompt the clinician to add immunosuppressive drugs such as methotrexate, azathioprine, CYC, or cyclosporine.^{33,41,47}

Cataracts may develop as a result of topical and systemic corticosteroid therapy. Surgical extraction and correction should be encouraged, especially in patients with hearing impairment from CS because they may depend on lip reading or sign language for communication.³⁷

Vestibuloauditory disease

A trial of systemic corticosteroid therapy is indicated for a patient in whom CS and hearing loss are newly diagnosed.^{30,33,48} Systemic corticosteroids are initiated at a dose of 1 to 2 mg/kg/day of prednisone or its equivalent (up to 60 mg)³³ for 2 weeks and then tapering of the dose in decrements of 5 to 10 mg every 1 to 2 weeks according to the patient's response. The dose can then be tapered to discontinuation over the next 3 to 4 months, provided that auditory acuity remains stable. Patients with refractory disease and recurrent episodes of hearing loss may require long-term daily corticosteroid therapy to maintain auditory function. Ideally, the dose of prednisone should be kept to 10 mg/day or less in these cases.

The use of immunosuppressive drugs as steroid-sparing agents is not uncommon. CYC, methotrexate, azathioprine, tacrolimus, leflunomide, and biologic drugs have been used successfully as adjunctive immunosuppressive therapy; however, their efficacy remains uncertain.³³ There are very few controlled trials, with the exception of a double-blind, placebo-controlled, randomized trial in which methotrexate therapy showed no significant efficacy in ameliorating autoimmune hearing loss.⁴⁹ Most evidence for the use of other disease-modifying antirheumatic drugs, including anti-tumor necrosis factor (TNF) and rituximab, is anecdotal and based on isolated case reports.⁵⁰⁻⁵² Some evidence indicates that infliximab can be effective in the treatment of hearing loss secondary to CS.⁵³ Etanercept is not effective in preserving or improving hearing loss, but it may improve word identification and recognition.⁵⁴

Hearing loss related to cochlear hydrops may respond to a course of diuretic therapy.^{37,46} Control of the symptoms of acute vestibular dysfunction can be facilitated with antihistamine or benzodiazepines and bed rest. In chronic cases, vestibular therapy with exercise activity may also prove useful.^{37,46} Cochlear implantation is the most successful surgical approach for end-stage hearing loss in patients with CS who have not responded to medical therapy or conventional hearing augmentation.³³

Systemic vasculitis

CS-related systemic vasculitis is treated with systemic glucocorticoids (prednisolone 1 mg/kg) in the same protocols as for any systemic vasculitis.

Medium-vessel vasculitis is treated with the same CYC regimen used for PAN.

For large-vessel vasculitides, cyclosporine (4 mg/kg/day or less) for a year or CYC (2 to 3 mg/kg orally) has been recommended. Methotrexate (15 to 25 mg/wk) has also been used.

Although biologic agents have been used in isolated case reports (anti-TNF, tocilizumab, rituximab), there is no convincing evidence to prove their efficacy.

Prognosis

The natural progression of the disease consists of an initial flare, which may last several weeks to months, followed by a chronic, slowly progressive phase. Ocular outcomes in patients with CS are excellent. Blindness occurs in less than 5% of eyes. In contrast, deafness is a frequent and debilitating outcome in CS and occurs in up to 52% of cases.⁵⁵ Corticosteroid therapy may improve the auditory outcomes. The vestibular manifestations improve in most patients with CS. However, some patients are left with persistent oscillopsia. Finally, although systemic vasculitis can be treated successfully, CS with vasculitis can be associated with a poor prognosis, especially in the context of large-vessel vasculitis with aortic incompetence.

CONCLUSION

PAN and CS are rare vasculitides with potential multisystem involvement. They are not associated with the presence of ANCA, and both require corticosteroid therapy in association with immunomodulators, depending on disease activity and severity. A high degree of clinical suspicion in patients with typical features, in conjunction with targeted investigations and confirmative histopathology or angiography, is helpful in distinguishing these two conditions from the large number of possible differential diagnoses. The main principles of managing patients with systemic vasculitis with regard to assessment of disease activity and damage, as well as the therapeutic paradigms involving CYC regimens for severe disease, are applicable to both these conditions. However, there is still a low level of evidence for therapeutic strategies because of the lack of large randomized controlled trials and the rarity of these important diseases.

ACKNOWLEDGMENTS

The authors would like to acknowledge the contributions of Dr. E. W. St. Clair and Dr. R. McCullum, who were the authors of the chapter on CS in the previous edition.

Polymyalgia rheumatica and giant cell arteritis

■ CORNELIA M. WEYAND ■ JÖRG J. GORONZY

POLYMYALGIA RHEUMATICA

- Polymyalgia rheumatica (PMR) is characterized by proximal muscle pain and stiffness that affects the neck, shoulders, and pelvic girdle.
- It is a forme fruste of giant cell arteritis (GCA) with molecular evidence of vascular inflammation yet absence of wall-infiltrating lymphocytes; PMR occurs in the same patient population that is at risk for GCA.
- Laboratory abnormalities (elevated erythrocyte sedimentation rate [ESR], C-reactive protein [CRP], and interleukin-6 [IL-6]) reflect an activated acute-phase response. Autoantibody assays are negative.
- Synovial inflammation, particularly of large joints, can occur but should raise suspicion for seronegative polyarthritis.
- Vascular symptoms necessitate temporal artery biopsy.
- Small doses of corticosteroids (10 to 20 mg/day) are sufficient to induce prompt and marked improvement of stiffness and pain.

GIANT CELL ARTERITIS

- This panarteritis of medium and large arteries is combined with an intense systemic inflammatory syndrome. Vasculitic lesions cause luminal occlusion and tissue ischemia or aortic aneurysm.
- Preferentially targeted vascular beds include branches of the external carotid, subclavian, common carotid, and vertebral arteries and the aorta.
- The major risk factor is age; patients are older than 50 years and the incidence continues to increase further with age.
- Typical features include new-onset headaches, scalp tenderness, jaw claudication, polymyalgia, fever, malaise, anorexia, and weight loss. Vascular occlusion is manifested as loss of vision, stroke, and ischemia of the upper extremities.
- Laboratory abnormalities include highly elevated acute-phase proteins (ESR, CRP, IL-6) and anemia.
- The diagnostic procedure of choice is temporal artery biopsy.
- Imaging of the aortic arch and the large vessels can be informative.
- Symptoms of systemic inflammation are explicitly sensitive to corticosteroid therapy, with dramatic improvement seen within 48 hours.

INTRODUCTION

Polymyalgia rheumatica (PMR) and giant cell arteritis (GCA) are two closely related inflammatory syndromes.^{1,2} In GCA, inflammatory infiltrates occupy the walls of medium-sized and large arteries and cause mural injury, luminal occlusion, and vascular stenosis. PMR is associated with intense muscle pain and stiffness affecting the shoulder and pelvic girdle; mild synovial and periarticular inflammation of proximal joints may be present in some patients, whereas in others the tissue site of inflammation remains unidentified. Both syndromes share laboratory abnormalities that reflect a vigorous acute-phase response and are critical for diagnosis and monitoring of affected patients.

PMR and GCA occur in the same patient population, thus suggesting common risk factors and pathogenic pathways. Significant progress has been made in discerning the molecular events of the vasculitic component. Vessel wall indigenous dendritic cells (DCs) that sense immunostimulatory danger signals have a checkpoint function and regulate the recruitment and

in situ activation of vasculitic T cells. The intense acute-phase response has prompted speculation that PMR and GCA are sequelae of infection, but attempts to implicate a single pathogen in the arterial tissue have not yet been successful, which raises the possibility of a diverse set of instigators.

The most significant risk factor for both syndromes is age; PMR and GCA are restricted to those 50 years and older, thus suggesting a critical role for aging, as well as for environmental and acquired factors, in the pathogenesis of the disease.

Over the past decades our ability to diagnose GCA accurately has improved, patient management has become more individualized, and the overall prognosis is good.

POLYMYALGIA RHEUMATICA

PMR is a syndrome of pain and stiffness that typically affects the proximal muscles of the shoulder and pelvic girdle. The muscles supporting the neck can be involved; myalgia of the torso is less common. PMR is frequently encountered in patients with GCA, in whom it may precede, follow, or accompany the manifestations of vasculitis. A small proportion (<10%) of patients with PMR and no clinical evidence of vasculitis are found to have frank vascular inflammation on biopsy. Laboratory tests show elevated acute-phase reactants, including the erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), and interleukin-6 (IL-6).^{3,4} An almost pathognomonic characteristic of the disease is prompt response to corticosteroids. For most patients, treatment can be discontinued after 1 to 2 years, although smoldering disease activity may persist.

The major diagnostic challenge in PMR is the lack of a pathognomonic test. Provisional diagnostic criteria (Box 156.1) have been developed that rely on nonspecific symptoms such as proximal muscle aching and stiffness and an acute-phase response, but these symptoms can occur in many other diseases.⁵ Abnormal ultrasound findings, particularly subdeltoid bursitis, were slightly more frequent in patients with PMR than in controls. In many patients PMR remains a diagnosis of exclusion that is made by minimizing the likelihood of other inflammatory conditions associated with a polymyalgia syndrome (Box 156.2). Some experts prefer a broad diagnostic definition of PMR and include patients with seronegative polyarthritis who have arthritis of the proximal joints or swelling and pitting edema on the dorsa of the hands and wrists; however, the outcome in these patients is different from that of the more narrowly defined PMR and resembles the outcome of seronegative rheumatoid arthritis (RA).

A critical aspect of diagnosing PMR lies in excluding GCA because these syndromes are so closely associated. Temporal artery biopsy should be performed in patients with suspicious vascular symptoms. Findings of GCA, as demonstrated by temporal arteritis on biopsy or typical vascular involvement on imaging studies, override a diagnosis of PMR. In any case, patients with PMR should be monitored for the emergence of vasculitis because GCA may develop even years later.

Clinical features

Ninety percent of patients with PMR have a sudden onset of muscle aching and stiffness affecting the neck, shoulders, and upper part of the arms. Frequently, they describe the pain as severe and disabling. Isolated discomfort in the pelvic girdle and thighs is less frequent. Symmetric myalgia is typical but not mandatory. Classically, the medial and distal parts of extremities are not affected, but the pain can radiate to the elbow and knee regions. The myalgia is most severe during the early morning hours; morning stiffness can be long lasting and incapacitating. Typically, the muscle pain is exacerbated by movement, such as using the arms or trying to rise from a

sitting position. On clinical examination, active range of motion of the proximal joints is restricted by pain and stiffness, but passive range of motion of the shoulders and hips is maintained. Little evidence exists for joint swelling or tenderness. Also, patients with PMR rarely lose muscle strength, a manifestation that warrants a workup for myositis.

Accompanying constitutional symptoms are frequent (>50% of patients) and include fatigue, malaise, anorexia, weight loss, and subfebrile temperatures.^{1,2} Fever, chills, and night sweats should prompt evaluation for underlying infection, malignancy, and vasculitic involvement.

BOX 156.1 POLYMYALGIA RHEUMATICA: PRELIMINARY DIAGNOSTIC CRITERIA

Required:

Age ≥50 years
Bilateral shoulder aching
Abnormal CRP and/or ESR

Major (2 points):

Morning stiffness >45 minutes
Absence of RF or ACPA

Minor (1 point):

Hip pain or limited range of motion
Absence of other joint involvement
Ultrasound findings of subdeltoid bursitis, biceps tendinitis, glenohumeral synovitis, trochanteric bursitis, or hip synovitis
Ultrasound findings in both shoulders

A score of 4 (or 5 if ultrasound is included) is suggestive for PMR.

ACPA, anti-citrullinated peptide antibody; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; RF, rheumatoid factor.

From Dasgupta B, Cimmino MA, Kremers HM, et al. 2012 Provisional classification criteria for polymyalgia rheumatic: a European League Against Rheumatism/American College of Rheumatology collaborative initiative. *Arthritis Rheum* 2012;64:943-54.

BOX 156.2 DISEASE ENTITIES WITH POLYMYALGIA SYMPTOMS

Rheumatoid arthritis
Rotator cuff syndrome
Osteoarthritis of the shoulder and hip joints
Fibromyalgia
Polymyositis/dermatomyositis
Spondyloarthritis
Systemic lupus erythematosus
Vasculitides
Paraneoplastic myalgias
Infection-associated myalgias
Statin therapy
RS3PE (remitting seronegative symmetric synovitis and pitting edema)
Parkinson disease
Hypothyroidism

Etiology and pathogenesis

Age is the major risk factor for PMR. The disease develops in individuals 50 years and older, and incidence rates continue to increase with advancing age.⁶ Two thirds of patients are female. Risk for the disease varies with geographic region, possibly reflecting environmental factors or clustering of risk genes in selected populations. The highest incidence rates have been reported in northern Europe, particularly the Scandinavian countries. In Olmsted County, Minnesota, a region enriched with immigrants from Scandinavia, yearly incidence rates have been estimated to be 59 per 100,000 people 50 years and older.⁶ Even higher incidence rates have been reported from the United Kingdom, up to 84 per 100,000 person-years.⁷

PMR is almost certainly a multigenic disease. Association with the HLA-DR4 haplotype has been reported in several populations, with variable results on whether this major histocompatibility complex class II haplotype confers only disease susceptibility or also plays a role in disease severity.

Central to the pathogenesis of PMR is the location where the inflammation occurs. This issue of tissue involvement remains unresolved, however. Systemic activation of the innate immune system is a key component of PMR, and a disease model of a primary defect triggering innate immunity is strongly supported by the presence of highly elevated acute-phase proteins (Fig. 156.1).² Patients with PMR have a high frequency of circulating activated monocytes/macrophages that produce proinflammatory cytokines such as IL-6.⁸ Because the frequency of cytokine-producing monocytes/macrophages in the circulation is indistinguishable from that in patients with GCA, systemwide monocyte activation is probably one of the early events in both diseases and not a consequence of local inflammation. Abnormal cytokine concentrations are found in the interstitial fluid of muscles, possibly a correlate of the myalgia characteristic of the disease.⁹ In addition, the temporal arteries of patients with PMR show evidence of local production of some inflammatory mediators even in the absence of an obvious inflammatory infiltrate by histomorphology.¹⁰ DCs in the adventitia of normal temporal arteries are activated and differentiated in patients with PMR.¹¹ They secrete chemokines, which are potent attractors of T cells, and can initiate adaptive immune responses in the vessel wall. When normal temporal arteries, arteries from PMR patients, and arteries from GCA patients were co-implanted into immunodeficient mice, vascular DCs in PMR arteries recruited and activated CD4+ T cells, whereas DCs in normal temporal arteries failed to promote T-cell stimulation (i.e., T cells from the GCA arteries moved into the PMR arteries but avoided the normal arteries). These experiments suggest that activation of vascular DCs is an initial step in establishing the vasculitis that has already occurred in PMR patients. The stimuli that activate vascular DCs in PMR are unknown, but these findings have reinitiated discussion about the role of infectious organisms, generally the most potent activators of DCs.

Laboratory studies

Acute-phase responses are examined by measuring the ESR or levels of CRP or IL-6. Other acute-phase reactants, including fibrinogen, serum amyloid A protein, and von Willebrand factor, are also elevated but do not appear to be more useful than CRP for diagnostic purposes or as biomarkers to

Fig. 156.1 CNS, central nervous system; CRP, C-reactive protein; DC, dendritic cell; IL, interleukin; MCP-1, monocyte chemoattractant protein-1. (From Weyand CM, Goronzy JJ. *Giant-cell arteritis and polymyalgia rheumatica*. *Ann Intern Med* 2003;139:505-15.)

monitor disease activity. Not all patients display abnormal findings with the standard inflammatory markers; about 10% have a normal ESR.⁴

Most patients have mild to moderate normochromic or hypochromic anemia. Frequently, platelet counts are elevated. Elevation of liver enzymes, particularly alkaline phosphatase, is part of the inflammatory syndrome. Serum creatinine levels and urinary sediments are normal. Despite intense muscle pain, muscle enzymes, electromyographic studies, and muscle biopsy do not show any evidence of muscle injury.

A useful diagnostic finding is the absence of autoantibodies. Antineutrophil cytoplasmic antibodies (ANCA) are rarely detected. Complement levels are normal. Antinuclear antibodies should prompt reassessment for an underlying connective tissue disease. Rheumatoid factors or antibodies to citrullinated peptides are not more frequent than expected in a population of healthy elderly individuals. Serum immunoglobulin concentrations are normal.

Imaging studies

Vascular imaging studies are performed primarily to exclude the vasculitic manifestations of GCA. They are indicated only if vasculitis is suspected clinically. The issue is particularly relevant for GCA of the distal subclavian arteries. Frequently, these patients come to clinical attention because of signs and symptoms of PMR, but about 50% have a negative temporal artery biopsy result.¹² Positron emission tomography with fluorine-18-labeled fluorodeoxyglucose (FDG-PET) has been reported to show enhanced metabolic turnover in the aortic wall and its large branches in a subset of PMR patients.¹³ Although this finding emphasizes vascular inflammation as a component of PMR, the specificity and clinical implications remain unclear. It is unknown whether the metabolic changes in patients with vasculitic inflammation are sufficiently distinct from those in atherosclerotic disease and whether PMR patients with vascular involvement based on PET should be managed differently.

In the subset of PMR patients with inflammation of periarticular structures, ultrasonography and magnetic resonance imaging (MRI) are sensitive diagnostic approaches.¹⁴ The most prominent findings are subdeltoid and subacromial bursitis; rarely, bicipital tenosynovitis and glenohumeral joint synovitis are found. Ultrasonography rapidly reveals accumulation of fluid in the bursae. Soft tissue thickening and edema can be visualized on MRI with a focus on axial T2-weighted sections.

Differential diagnosis

Polymyalgic syndromes are diagnosed frequently and require careful evaluation (see Box 156.2). The current diagnostic criteria (see Box 156.1) are only moderately helpful in identifying patients with “true” PMR. In a significant proportion of patients seen initially with polymyalgia, the diagnosis is revised at follow-up.¹⁵ PMR and some forms of RA are particularly difficult to distinguish. Patients with late-onset RA tend to have preferential involvement of the proximal joints, particularly in early stages of the disease, thus making it almost impossible to separate them from patients with PMR. With progression of the disease, peripheral and erosive arthritis often develop in RA, but not in PMR.

Closely related to PMR is the remitting seronegative symmetric synovitis and pitting edema (RS3PE) syndrome, a variant of seronegative RA characterized by symmetric peripheral synovitis and tenosynovitis causing pitting edema on the dorsa of the hands and wrists and, less frequently, the ankles and feet. Patients with RS3PE respond explicitly well to low doses of corticosteroids. Imaging studies demonstrate the intense tenosynovitis component of this polyarthritis. The disease usually remains nonerosive.

A combination of muscle pain, stiffness, and inflammatory markers is fairly common in patients with systemic lupus erythematosus; identification of antinuclear antibodies and organ manifestations typical of connective tissue disease (especially skin, lung, or kidney disease) makes it relatively easy to distinguish these syndromes. Marked constitutional symptoms, including fever, weight loss, depression, and malaise, in combination with muscle soreness is common in many vasculitic syndromes, including GCA.

Inflammatory myopathies typically cause loss of muscle mass and strength. Elevated muscle enzyme levels should prompt further evaluation by electromyography and muscle biopsy.

Patients with diffuse muscle pain and stiffness need to be interviewed carefully for their medication history. Myalgia, muscle weakness, and cramping develop in 1% to 5% of patients taking statins (3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors).¹⁶ In general, the pain is more diffuse, lacks preference for proximal muscle groups, and does not display a circadian rhythm; muscle enzyme levels can be normal or elevated. The myalgia can persist after withdrawal of statin therapy.

Physicians should be alert to the possibility of paraneoplastic myalgia. Profound weight loss, drenching night sweats, and an incomplete response to corticosteroids provide clues for further assessment. An elevated ESR because of a paraprotein can be the first indication of lymphoproliferative disease. Also, patients should be examined for an underlying infection that may be causing fatigue, malaise, fever, muscle pain, weight loss, and inflammatory markers.

Treatment

A typical feature of PMR is a prompt, profound response to corticosteroids. For most patients, initial prednisone doses of 10 to 20 mg or equivalent are sufficient to control the myalgia.^{3,4} Infrequently, patients require higher doses. Almost complete resolution of symptoms is usually experienced within 2 to 3 days, but clinical responses to lower prednisone doses can be delayed. Incomplete responses or recurrence of symptoms during the early treatment phase should increase suspicion about the diagnosis or raise the possibility of GCA.

The initial doses are maintained for 2 to 4 weeks, followed by careful tapering. Normally, the corticosteroid dose can be reduced by 10% every 2 to 4 weeks. About 50% of patients experience disease flares as the dosage of corticosteroids is decreased. Monitoring of the ESR and CRP can help in assessing the inflammatory burden. With improvement, the ESR returns to the normal range and the CRP level improves but frequently does not completely normalize, a finding suggesting continuous smoldering disease activity. Clinical symptoms (especially muscle soreness and malaise) are used as the main indicators for therapy. Recurrent myalgia or a rise in acute-phase markers frequently require only minute increases in corticosteroid doses. Unresolved questions are whether smoldering systemic inflammation beyond 1 to 2 years requires treatment and, if so, which immunosuppressive method can be safely administered long-term. Very low dosages of corticosteroids (prednisone 1 to 3 mg/day) are often sufficient for adequate control of symptoms in these chronically treated patients.

Use of methotrexate (MTX) as a corticosteroid-sparing agent has been addressed in a randomized, doubled-blind, placebo-controlled trial. Prednisone (25 mg/day starting dose) was tapered off within 24 weeks with dose adjustment in the event of flare-up. Patients were randomized to receive 10 mg of MTX per week for 48 weeks or placebo. Outcome was assessed after 18 months. Significantly more patients in the MTX group were not taking corticosteroids, and significantly fewer experienced any flare-ups. However, the rate and severity of adverse effects were similar and the corticosteroid-sparing effect was modest (cumulative 2.1 g of prednisone in the MTX group and 2.9 g in the placebo group), which raises the question of whether the benefits from MTX are clinically meaningful.¹⁷ Although in a long-term follow-up study 65% of patients had at least one corticosteroid-related adverse effect, mortality rates in PMR patients are not increased, and even longer than expected survival has been reported in a Scandinavian cohort.¹⁸ Efforts should concentrate on ensuring that patients receive the minimally effective corticosteroid doses. Given the age and comorbid conditions of individuals at risk for PMR, the use of aggressive immunosuppressants should be considered with great caution. Since patients with PMR experience increased bone turnover, even before corticosteroid therapy,¹⁹ management should include calcium and vitamin D supplementation and other bone-sparing treatments if indicated by bone mineral density measurements.

GIANT CELL ARTERITIS

GCA is an inflammatory vasculopathy that affects large and medium-sized arteries.²⁰ Almost all patients have signs and symptoms of systemic inflammation manifested as nonspecific constitutional symptoms with an intense acute-phase response, including highly elevated ESR and CRP values and anemia. Diagnostic criteria have been developed to distinguish GCA from other vasculitides²¹; however, they were intended for investigative studies and not for establishing the diagnosis in individual patients (Box 156.3).

The vascular component of GCA results from a granulomatous arteritis that elicits a response to injury in the affected vessel wall.²² In medium-sized arteries, this leads to hyperplasia of the intima, luminal occlusion, and ischemia. In the aortic wall, inflammation causes structural damage that eventually results in aneurysm formation and dissection. Selected vascular territories, such as the aorta and its upper branches, are most susceptible to GCA. Typically, branches of the external carotid, including the temporal arteries, are involved. The most severe complications of GCA are loss of vision and stroke. Blindness is potentially preventable if the disease is recognized and treated promptly, thus emphasizing the need for a high index

BOX 156.3 AMERICAN COLLEGE OF RHEUMATOLOGY 1990 CRITERIA FOR THE CLASSIFICATION OF GIANT CELL ARTERITIS

The presence of 3 or more of the following 5 criteria assigns a vasculitis patient to the diagnosis of GCA

- Age at disease onset ≥ 50 years
- Headache of new onset or new type
- Tenderness or decreased pulsation of the temporal artery
- Elevated erythrocyte sedimentation rate (>50 mm/hr)
- Histologic changes of arteritis (either granulomatous lesions, usually with multinucleated giant cells, or diffuse mononuclear cell infiltration)

From Hunder GG, Bloch DA, Michel BA, et al. The American College of Rheumatology 1990 criteria for the classification of giant cell arteritis. *Arthritis Rheum* 1990;33:1122-8.

of clinical suspicion and familiarity with the typical and atypical manifestations of this vasculitis.

The overall prognosis of patients with GCA is good. Survival rates of patients with GCA are equivalent to those of an age-matched population.²³ Notably, acceleration of atherosclerosis, which complicates the course of many rheumatic diseases, has not been found in patients with GCA.

Clinical features

GCA is a disease of the elderly and does not usually occur before the age of 50 years. The mean age at diagnosis is 70 to 75 years, and two thirds of patients are female. Frequently, the disease begins insidiously, with symptoms gradually increasing in severity over a period of weeks or months. In some cases the onset is abrupt and the first manifestation is a major complication, such as loss of eyesight. Symptoms can wax and wane and resolve temporarily, even in the absence of treatment. The spectrum of initial disease manifestations is broad (Table 156.1),^{1,2} and physicians need to be alert to not miss subtle manifestations of vascular insufficiency or clinical symptoms.

Most patients come to clinical attention because of headaches, scalp tenderness, and PMR; fever, malaise, anorexia, and weight loss are also frequent manifestations.²⁴ If the arteritis involves the cranial vasculature, headaches and ischemia of the eye, brain, and cranial muscles dominate the findings. If extracranial arteries are the primary target, patients often have an aortic arch syndrome characterized by impaired blood flow to the upper extremities.¹² If the major disease component is systemic inflammatory syndrome, vascular complications may be minimal and the clinical features are those of a wasting syndrome or fever of unknown origin. Manifestations of vascular inflammation are helpful for the clinician in predicting whether a patient has GCA. Signs of systemic inflammation are obviously less specific but are a useful hint in screening for suspected cases (Fig. 156.2).

Cranial arteritis

The former names of GCA, temporal arteritis and cranial arteritis emphasized the inflammatory stenosis of distal branches of the thoracic aorta. Because the disease targets branches of the external carotid artery, patients complain of headaches, scalp tenderness, jaw claudication, and tongue claudication. The blood supply to the orbit can become compromised and cause visual loss.²⁵ Stenotic lesions in the vertebral and basilar arteries produce central nervous system ischemia, vertebrobasilar insufficiency, transient ischemic attacks, and strokes.²⁶

Patients describe their headaches as being diffuse or localized, usually in the temporal, occipital, or periorbital areas. The headaches can be severe, may be refractory to standard analgesics, and can interfere with sleep. Scalp tenderness is frequent and at times localized over the temporal and occipital arteries, but it can also be distributed diffusely. The pressure from wearing glasses may be intolerable. Insufficient blood flow to the masseter and pterygoid muscles causes jaw claudication, a rather specific finding for GCA. Talking or chewing elicits muscle cramping and pain that forces the patient to interrupt conversations or meals. A similar mechanism can lead to tongue claudication, rarely complicated by frank gangrene. A sore throat and painful dysphagia may indicate ischemia of the pharynx.

The true incidence of ocular involvement in GCA is poorly defined, but it is estimated that up to 15% of patients experience ophthalmic complications.²⁵ Ischemia in the territory of the ophthalmic artery is the leading cause of ocular problems, but ischemia anywhere along the visual pathways can threaten eyesight. The visual loss is pain free, can be partial or complete, be unilateral or bilateral, and is generally irreversible. The most common cause is anterior ischemic optic neuropathy secondary to occlusion of the

TABLE 156.1
Clinical features of giant cell arteritis

Clinical feature	Overall frequency	Seen predominantly in
Manifestations of vascular injury		
Headaches:		
Different patterns; often severe, sometimes throbbing; can be localized	+++	CA
Scalp tenderness:		
Often temporal; elicited by combing or by touching or wearing glasses; the temporal artery can be thickened, tender, or nodular	++	CA
Jaw claudication:		
Induced by chewing and prolonged talking	++	CA
Ocular symptoms:		
Partial or complete visual loss, amaurosis fugax, or ocular motor deficit; blindness, unilateral or bilateral; usually permanent	+	CA
Dysphagia:		
Sore throat, painful swallowing	+	CA
Respiratory symptoms:		
Dry, nonproductive cough	+	CA
Limb claudication:		
Ischemic pain with use of the arms, paresthesias, color changes, rarely lower extremity claudication	+	
Absent or asymmetric pulses	+	LVA
Asymmetric blood pressure readings	+	LVA
Ischemia of the central nervous system:		
Vertebrobasilar insufficiency, dizziness, imbalance, cortical blindness, confusion	+	CA
Tongue claudication	+	CA
Aortic dilation and regurgitation	+	LVA
Myocardial infarction	+	
Peripheral neuropathy	+	
Tissue gangrene:		
Scalp, tongue, or digits	+	
Manifestations of systemic inflammation		
Intense acute-phase response:		
Elevated erythrocyte sedimentation rate; elevated levels of C-reactive protein, interleukin-6, and other acute-phase proteins; thrombocytosis; elevated liver function test results	+++	CA, SISA, LVA
Normocytic, normochromic anemia	++	SISA, CA
Polymyalgia rheumatic:		
Stiffness and pain in the muscles of the shoulders, pelvic girdle, and neck; rarely the torso	++	CA, SISA, LVA
Wasting syndrome:		
Anorexia, weight loss, fever, malaise, night sweats, depression	++	SISA
Synovitis of peripheral joints:		
Mostly the wrists	+	

CA, cranial arteritis; LVA, large vessel arteritis; SISA, systemic inflammatory syndrome with arteritis.

Data from Weyand CM, Goranzy JJ. Giant-cell arteritis and polymyalgia rheumatica. *Ann Intern Med* 2003;139:505-15.

Fig. 156.2 Jaw claudication, diplopia, and an enlarged temporal artery (TA) are helpful findings in distinguishing patients likely to have giant cell arteritis. Likelihood ratios near 1 (black dotted line) indicate that the characteristic occurred equally in patients with positive and negative TA biopsy results. Synovitis occurred more frequently when biopsy specimens were negative. (From Smetana GW, Shmerling RH. Does this patient have temporal arteritis? *JAMA* 2002;287:92-101.)

ophthalmic artery or the posterior ciliary arteries supplying the optic nerve. Ophthalmologic examination finds a pale disc edema resulting from ischemic damage to the optic nerve head. Preceding symptoms may include amaurosis fugax or fleeting visual blurring with exercise, but the loss of vision is frequently sudden. Patients with facial pain, periorbital pain, and swelling may be at higher risk for ischemic ophthalmic complications. Diplopia and ocular motor imbalance are recognized manifestations of GCA that have been estimated to occur in 2% to 15% of patients and sometimes precede the visual loss.²⁷ The ophthalmoplegia can be unilateral or bilateral; most commonly involved is the oculomotor nerve, which leads to third nerve palsy.

Arteritis of the vertebral and basilar arteries can cause brain stem ischemic episodes or strokes, often complicated by dizziness, balance problems, vertigo, and oculomotor defects. Infrequent neurologic manifestations of GCA include mononeuropathies and peripheral neuropathies.

Pulmonary symptoms occur less frequently, but ischemia of the bronchial tree can result in a dry, nonproductive cough.

Large-vessel arteritis and aortitis

A large-vessel pattern of GCA can overlap with a cranial pattern or be the dominant manifestation of the disease.²⁸ Stenotic lesions in the distal subclavian arteries, the axillary arteries, and the brachial arteries are typical of GCA and are relatively easy to distinguish from the more proximal lesions of Takayasu arteritis and from atherosclerotic disease. Lower extremity arteries are infrequently affected.²⁹

Large-vessel GCA leads to aortic arch syndrome, with ischemia of the upper extremities sometimes being manifested as pulseless disease.¹² Activities involving the arms, such as brushing the teeth, working overhead, or playing the piano, induce ischemic pain and force the patient to rest. Blood pressure readings may be asymmetric, bilaterally diminished, or absent. Raynaud phenomenon-like symptoms consisting of paleness, a bluish discoloration, and dysesthesias of the hands are common. Tissue gangrene, predominantly affecting the fingertips, can also occur. Bilateral manifestations are common, but unilateral involvement or asymmetric patterning is possible. About 50% of patients with subclavian-axillary GCA have negative temporal artery biopsy findings and also lack cranial clinical signs and symptoms, such as headaches, jaw claudication, and visual symptoms.¹²

Aortitis has been estimated to complicate GCA in 10% to 20% of patients, but this figure is probably underestimated. In particular, subtle forms of aortic wall inflammation remain clinically silent. The thoracic part of the aorta is more commonly affected than the abdominal part.²⁹ In contrast to medium-sized arteries, the aorta responds to GCA with loss of the medial layer, destruction of the elastic membrane, luminal dilation, and eventually, aneurysm formation. Late clinical features such as aortic valve insufficiency, aortic dissection, and rupture of an aortic aneurysm can each be the first sign of GCA aortitis. Histomorphologic features of giant cell vasculitis in resected aortic aneurysms may also lead to the diagnosis.

In view of the potentially life-threatening complications of GCA aortitis, patients with established GCA should be monitored for aortic involvement. Modern imaging modalities, including computed tomography (CT) and MRI, offer fast information about the diameter of the aorta, wall irregularities, dissection, and wall thickness.³⁰ In contrast to Takayasu arteritis, GCA aortitis causes less pronounced wall thickening.

Systemic inflammatory syndrome with arteritis

Forty percent to 50% of patients with GCA exhibit fever, malaise, fatigue, weakness, anorexia, weight loss, and depression. In a specific patient subset these constitutional symptoms were found to be the major disease manifestations.³¹ Frequently, these patients are not initially seen by a rheumatologist but are referred when a workup for malignancy and chronic infection has remained negative. In about 15% of cases, fever of unknown origin is the initial manifestation. In such patients, physical examination of scalp arteries may provide normal results. Nevertheless, GCA should be suspected if the patient falls into the at-risk age group. The preferred diagnostic procedure is temporal artery biopsy even if clinical symptoms of vascular ischemia are lacking. Histomorphologic evaluation may demonstrate vessel wall inflammation without intimal hyperplasia. Patients with this variant of GCA may be at lower risk for the development of blindness.³²

Polymyalgia rheumatica

PMR symptoms develop in approximately 50% of patients with GCA; 25% already have proximal myalgia at the time of initial diagnosis. In an estimated 10% of patients with isolated PMR, GCA will subsequently be diagnosed. Disease flares in patients with GCA undergoing prednisone taper are frequently manifested as myalgia, not as ischemic complications.

In a meta-analysis that examined clinical symptoms for their sensitivity and specificity in predicting the results of temporal artery biopsy, synovitis was a negative predictor of arteritis.²⁷ This study emphasizes the fact that joint inflammation is not a manifestation of GCA and indicates a different diagnosis (see Fig. 156.2).

Etiology and pathogenesis

GCA is an immune-mediated disease with abnormalities in the innate and adaptive arms of the immune system.²⁰ No single instigator of the chronic immune response in the vascular wall has been identified, nor has a single abnormality in the host's immune system been found. Multiple risk factors predispose individuals to this inflammatory vasculopathy. The major risk factor is age, and incidence rates increase after the age of 50 years over the ensuing decades.³³ The immune system changes dramatically with age, and immune regeneration and function decline steeply during later life. How immunosenescence affects risk for GCA is not known.

Geographic variations in incidence rates point toward Scandinavian ancestry as an important risk factor.³⁴ Incidence rates are the highest in Iceland, followed by Sweden, Norway, and Denmark; rates in the United States correlate with northern European immigration patterns. Disease susceptibility in blacks is low. Takayasu arteritis, another type of granulomatous vasculitis, is more likely to develop in individuals of Asian origin.

Genetic polymorphisms that would explain the ethnic predisposition have not been identified. Like many other autoimmune syndromes, GCA is an HLA class II-associated disease.³⁵ PMR and GCA display a similar association with the HLA-DR4 haplotype, thus suggesting a role of HLA-DR4-linked genes in predisposing individuals to the systemic inflammatory syndromes but not in facilitating pathways of vessel wall inflammation.

Efforts to identify infectious organisms in the inflamed arteries have not yielded consistent results.³⁶ Studies describing the identification of microbial gene sequences in affected arteries have generally not been confirmed in subsequent research.

Pathogenic mechanisms

Over the past decade, pathogenic pathways for the vasculitic process have been dissected.^{20,37} The emerging disease model proposes three critical checkpoints: innate immune cells in the vessel wall facilitate the early steps of immune system activation, adaptive immune responses mediate *in situ* CD4+ T-cell stimulation, and structural parameters of the vessel wall provide the microenvironment for deregulated innate and adaptive immunity (Fig. 156.3).

In normal, noninflamed temporal arteries, the wall not only consists of endothelial cells, vascular smooth muscle cells, fibroblasts, and matrix but also harbors a DC population in the adventitia at the media-adventitia border. DCs form a ringlike structure around the circumference of the vessel in a discontinuous, skipping pattern. Their phenotype identifies them as specialized tissue DCs with both similarities to and differences from Langerhans cells and DCs in lymphoid tissue.

Fig. 156.3 DC, dendritic cell; IFN- γ , interferon- γ .

DCs function primarily as sentinels that sense disturbances in the tissue microenvironment and report this to the immune system. DCs are equipped with many kinds of receptors through which they recognize molecular patterns shared by infectious microbes. They also respond to tissue damage and are suspected to have a broad role in tissue homeostasis. The functional properties of vascular DCs have been studied in an experimental model in which human temporal arteries were implanted into immunodeficient mice. Injection of bacterial products such as lipopolysaccharides into the artery-mouse chimeras triggers vascular DCs to initiate the production of chemokines and recruit T cells to the artery wall.¹¹ The recruited T cells undergo activation in the adventitia,³⁸ proliferate, and produce CD40L and interferon- γ (IFN- γ). This model recapitulates the early steps in vasculitis and defines the wall-residing DCs as gatekeepers. Vascular DCs have emerged as a prime candidate in determining why some blood vessels are more prone to be targeted by GCA and why the inflammatory infiltrates are often arranged in a skipped distribution. Each vascular bed expresses a unique profile of Toll-like receptors (TLRs), which not only assigns pathogen-sensing function to arteries but also gives each vascular territory an immunologic identity.³⁹

Signals recognized by vascular DCs critically determine the architecture of emerging vasculitis. TLR4 ligands induce a pattern of panarteritis, whereas stimulation of TLR5 results in perivasculitis.⁴⁰ Studies of temporal artery biopsy specimens have also suggested two distinct inflammatory patterns, thus supporting the concept of GCA subtypes related to differences in initial disease instigators.⁴¹

In fully developed GCA, dense infiltrates of CD4+ T cells, macrophages, and DCs crowd the wall structure. CD4+ T cells release IFN- γ and undergo clonal expansion, with identical T-cell clones growing in both temporal arteries of the patient. These T cells orchestrate an immune response that eventually leads to wall damage and an arterial response to injury. At least two T-cell differentiation pathways, type 1 helper T cell (Th1) and Th17, have been implicated in vasculitic T-cell responses.⁴² Cytokine patterns can be quite diverse and correlate with the clinical manifestations.⁴³ Patients with high tissue IFN- γ levels often have intense intimal hyperplasia and, accordingly, exhibit tissue ischemia, including visual symptoms and jaw claudication. Patients with a predominance of systemic inflammation, often with minimal luminal occlusion, typically produce large amounts of IL-2 but less IFN- γ in the tissue. In longitudinal studies the cytokine pattern was not stable over time. In early untreated GCA, a broad array of cytokines characteristic of the Th1 and Th17 pathways were found, including

macrophage-derived IL-1, IL-6, IL-12, and IL-23 and T cell-derived IFN- γ and IL-17. Six months after initiation of treatment, 80% of all patients still had evidence of vascular inflammation, but only the Th1 and not the Th17 response persisted.⁴²

Recruitment of CD4+ T cells to the adventitia of the blood vessel by activated DCs is a condition *sine qua non* for amplifying and maintaining the inflammation. Depletion of T cells in mice implanted with GCA-affected temporal arteries disrupts the disease process, inhibits macrophage activity, and leads to resolution of the granulomatous infiltrates.⁴⁴ T-cell recruitment or function (or both) is at least in part dependent on signals involving the NOTCH pathway. Treatment of the human tissue-mouse chimera with a NOTCH cleavage inhibitor or a soluble NOTCH ligand, Jagged1-Fc, abrogated the T-cell response in the artery.⁴⁵ DCs are necessary to continuously support T-cell activation; depletion of DCs in GCA tissue very effectively abrogates the vasculitis.¹¹

Macrophages settle in distinct microenvironments of the arterial wall.⁸ Depending on their positioning in the adventitia, media, or intima, they commit to different functional profiles resembling differentiation into M1 and M2 macrophages. Adventitial macrophages specialize in producing IL-6 and IL-1. Medial macrophages actively secrete reactive oxygen intermediates. Oxidative stress contributes to the destruction of endothelial and vascular smooth muscle cells. Medial macrophages also produce metalloproteinases, which are probably relevant in digesting elastic membranes and would explain the typical finding of fragmented elastic membranes in affected arteries. These macrophages and the macrophage-derived multinucleated giant cells that are typically localized at the media-intima border release growth and angiogenesis factors, such as platelet-derived growth factor and vascular endothelial growth factor, and support the maladaptive arterial response that eventually results in outgrowth of the intimal layer and vessel occlusion.²²

Intimal hyperplasia requires mobilization, migration, and proliferation of myofibroblasts. Growth factors facilitate these essential steps and thus have a direct impact on the degree of intimal obstruction. Intimal layer outgrowth is possible only if sufficient oxygen is supplied. Under physiologic conditions, the arterial intima and media are avascular structures, whereas the adventitia contains a vasa vasorum network. GCA-affected temporal arteries often show a newly formed microvessel network commonly arranged in the distal part of the intima but also extending into the media. The degree of neovascularization in the inflamed vessel wall is closely correlated with the amount of IFN- γ produced by activated CD4+ T cells.²²

Investigations

Pathology

Arterial biopsy remains the most specific diagnostic procedure (see Box 156.3). Temporal artery biopsy, if done correctly, is a low-risk procedure with high diagnostic yield. Therefore, a clinical diagnosis should always be confirmed by tissue biopsy. Patients in whom the diagnosis of GCA is based on only laboratory abnormalities and clinical features often become challenges when long-term therapy is required because their diagnosis remains uncertain. Guided by clinical examination, the side with more abnormal findings (headaches and tenderness or nodularity of temporal vessels) should be sampled first. Because GCA can produce skip lesions, an arterial segment 2 to 3 cm in length should be harvested. Immediate evaluation of frozen sections from this segment enables one to make the decision whether to proceed with biopsy of the second side. However, in large case series the yield of biopsy of the second side has been low, thus providing the rationale for sparing the second side for possible future biopsy if suspicion for GCA persists or arises again.⁴⁶ In selected cases the occipital artery is sampled.

Histomorphologic evaluation of inflamed temporal arteries finds T-cell and macrophage infiltrates in the wall. Lymphocytes usually accumulate in the media. Multinucleated giant cells are found in about 50% and are not required for the diagnosis. Classically, such giant cells localize at the media-intima border, near fragments of the internal elastic lamina. Hyperplastic intima can occlude the vascular lumen, but in some cases it remains completely uncompromised. Isolated adventitial lymphocytic infiltrates can be a significant finding and be sufficient for a diagnosis of vasculitis. Some pathologists describe “healed arteritis” when finding thickened intima, fragmented elastic membranes, and medial scarring. Arteritis in the temporal artery may represent a vasculitis other than GCA. Fibrinoid necrosis is unusual for GCA and suggests another vasculitic entity, such as panarteritis nodosa or ANCA-associated vasculitis, which needs to be confirmed further by appropriate studies.

An important question relates to the timing of arterial biopsy and whether corticosteroid therapy can lead to false-negative findings. Preferably, biopsy should be performed as early as possible in an untreated patient. However, therapy should not be postponed in patients at risk for loss of vision or other serious complications. Retrospective studies examining biopsy specimens from corticosteroid-treated patients have reported persistence of inflammatory infiltrates.⁴⁷ Studies of mice implanted with inflamed temporal arteries have also demonstrated that eliminating vascular inflammation is exquisitely difficult and requires very high doses of corticosteroids.⁴⁸ Repeated biopsies in a small longitudinal study have shown persistence of the inflammation for more than 6 months in the majority of patients.⁴² Biopsies should therefore be performed in patients already receiving therapy if indicated. Whether corticosteroids can lead to the resolution of more subtle findings is unknown.

Laboratory studies

Acute-phase proteins are helpful markers in diagnosing and managing GCA. Although acute-phase proteins are nonspecific markers of immune system activation, high ESR values in an elderly individual can prompt consideration of GCA. Not all patients have high or even abnormal ESR results. Up to 25% of patients with biopsy-confirmed GCA have a normal ESR before corticosteroids are started.⁴⁹ Normal ESR results do not exclude the diagnosis and the need for tissue biopsy in clinically suspected patients.

Other acute-phase reactants, such as CRP, may be helpful biomarkers. IL-6, a cytokine that induces the production of acute-phase proteins, is highly elevated in patients with GCA and PMR and may be more sensitive in detecting low-grade inflammation⁴⁹; however, circadian rhythm makes it more difficult to interpret. Numerous other acute-phase proteins, including fibrinogen, haptoglobin, orosomucoid, α_1 -antitrypsin, serum amyloid A, and von Willebrand factor, have all been reported to be elevated in GCA with no evidence of disease specificity. A normochromic, normocytic anemia can be an initial feature. Thrombocytosis occurs frequently. In addition, elevated liver function test results, especially for alkaline phosphates, is seen in many GCA patients. Serum albumin levels can be decreased.

No autoantibody is pathognomonic of GCA, and therefore autoantibody studies are useful only for excluding other diseases. Rheumatoid factors and antibodies to citrullinated peptides are negative. ANCAs have value in differentiating GCA from other arteritides. Reports of an increased frequency of antiphospholipid antibodies are of unknown significance.

Imaging studies

Blood vessel imaging has gained importance as a method for assessing the extent of vasculitis or even for making a diagnosis of GCA. Even though the vast majority of patients with GCA and cranial symptoms have positive

temporal artery biopsy findings, histology is negative in about 50% of patients with an extracranial distribution.¹² In these patients the subclavian, axillary, vertebral, and occasionally the carotid arteries are the primary targets. Imaging of these vessels in biopsy-negative patients can establish the diagnosis. Detection and monitoring of aortic arch involvement depend heavily on imaging procedures. Typical findings include long-segment narrowing of the vascular lumen of primary and secondary branches, often with smooth tapering at both ends (Fig. 156.4).³⁰ The pattern of involvement provides crucial hints. Lesions in the distal subclavian, the axillary, and the proximal brachial arteries are typical of GCA. Patients with cerebral ischemia need evaluation for stenotic lesions of the vertebral and basilar artery system. GCA does not affect intracerebral arteries.

Conventional radiographic angiography remains superior for detailed assessment of vessel anatomy and luminal status, but it is usually required only for preoperative evaluation. Digital subtraction angiography, formerly used for quick assessment, has been replaced by magnetic resonance angiography (MRA). Not limited by axial, coronal, and sagittal planes, MRA is the preferred procedure for assessing the aortic branches and neck vessels. CT angiography can give rapid information about aortic dimensions, as well as wall irregularities and thickening. Contrast media-induced nephrotoxicity is a disadvantage of this approach.

High-resolution MRI or duplex ultrasonography can be applied to evaluate the temporal artery directly for signs of inflammatory changes. A dark halo around the lumen of the temporal artery on ultrasound has been associated with inflammatory edema and wall thickening. However, both imaging procedures are not sufficiently sensitive and may miss the more challenging patients with subtle vasculitis. The sensitivity of detecting GCA with MRI is only about 80%.⁵⁰ In a prospective study, ultrasonography did not increase the diagnostic accuracy of a careful physical examination, thus indicating that it cannot replace temporal artery biopsy.⁵¹ A large recent meta-analysis of 17 studies with close to 1000 patients estimated a sensitivity of just 75% with a specificity of 83%.⁵²

A critical issue in the management of GCA is how to quantify disease burden and activity. Much hope has been placed on T2-weighted MRI as a means of imaging wall thickness, wall edema, and potentially, blood flow in the inflamed wall as an indirect marker of inflammation. However, studies in patients with Takayasu arteritis have questioned the value of MRI as a means of measuring disease activity.⁵³ FDG-PET indicates inflammatory activity in the vessel wall in GCA and PMR.⁵⁴ Increased uptake of labeled glucose by inflammatory cells provides the underlying mechanisms of detection, but no properly designed studies have been conducted to assess this procedure's specificity and sensitivity. Specifically, it is unknown whether subtle inflammation in atherosclerotic lesions can be distinguished from active arteritis in an elderly patient population expected to have an increased atherosclerotic burden.

Treatment

Corticosteroids

Corticosteroids are highly effective in suppressing both the vascular and systemic components of GCA. The incidence of blindness, the most feared complication of GCA, declined considerably when corticosteroid therapy was introduced. Corticosteroid therapy should be started promptly at diagnosis and not be delayed in patients with progressive disease or impending visual loss. In almost all patients with GCA, corticosteroids induce such rapid symptomatic relief that the response to corticosteroid therapy has been considered a diagnostic criterion. Disease manifestations related to the systemic inflammation and PMR respond within 48 to 96 hours, often with dramatic relief. Manifestations related to impaired blood flow, such as jaw claudication, extremity claudication, and visual complications, may show delayed or no response because luminal occlusion of blood vessels by intimal hyperplasia is irreversible. However, corticosteroids may reduce tissue edema, enhance some blood flow, and restore some function.

Almost all patients respond to 40 to 60 mg of prednisone (or equivalent) per day given as a single morning dose. Higher starting doses are sometimes used in patients with visual loss or transient amaurosis. Once all the reversible symptoms resolve, usually after about 1 month of therapy, and the ESR and CRP improve by at least 50%, the corticosteroid doses are tapered. Patients initially need to be evaluated at 2- to 4-week intervals and should be monitored for clinical symptoms and laboratory evidence of inflammation. Corticosteroid doses are titrated according to disease activity; in nearly all cases prednisone can be tapered by 10% every 2 weeks. Once patients reach a daily dose of 10 mg, further tapering should be very gradual, about 1 mg per month. Alternate-day dosing is unsuccessful and should not be attempted. Recurring symptoms and rising levels of acute-phase proteins often complicate corticosteroid tapers that are too rapid. Most often, disease flares require

Fig. 156.4 Imaging studies for giant cell arteritis. (a) Occlusion of the axillary-brachial junction. The angiogram shows irregularity of the right subclavian artery with occlusion at the axillary-brachial junction and formation of collateral vessels. (b) Digital subtraction image. (c) A magnetic resonance angiogram of the great vessels shows narrowing of the subclavian artery distal to the origin of the vertebral artery. (d) A contrast-enhanced computed tomographic image of the chest shows pronounced ectasia of the ascending aorta, minimal thickening, and irregularity of the wall.

only moderate increases in corticosteroid doses.⁴⁹ Fortunately, disease recurrence is manifested mostly as PMR or constitutional symptoms. Once adequate corticosteroid therapy is implemented, the risk for visual loss is low.

Throughout corticosteroid tapering, monitoring of the ESR can be helpful in assessing disease activity, but values frequently remain normal even in a clinical flare (Fig. 156.5).⁴⁹ Measurement of CRP and IL-6 appears to be more sensitive in detecting inflammation; however, studies have demonstrated that IL-6 levels remain elevated in many patients who are clinically asymptomatic.^{4,49} Thus, mildly elevated acute-phase markers alone may not justify increased treatment.

GCA is not a self-limited disease; smoldering disease activity may persist even after 2 years of corticosteroid treatment. Some patients require long-term low-dose corticosteroid treatment, but the need for high doses for prolonged periods is infrequent and should be assessed carefully. Whether low-grade inflammation, detected by sensitive markers such as CRP or IL-6, warrants continued immune system suppression is unknown. Findings of aortic dissection/aneurysm a decade after initial diagnosis signal the chronicity of the disease process and may encourage long-term treatment to control the inflammatory activity.²⁸ This issue needs to be approached in appropriately designed clinical trials to weigh its risks and benefits.

A recent randomized controlled trial examined the therapeutic efficacy of initial pulse corticosteroids.⁵⁵ The goal was to explore whether initial high doses of corticosteroids (15 mg/kg methylprednisolone intravenously, or approximately 1000 mg/day for an average 70-kg patient) on 3 consecutive days would shorten the disease course and reduce long-term corticosteroid requirements. The induction regimen allowed rapid tapering of oral prednisone to less than 5 mg/day within 36 weeks. Most importantly, the percentage of patients off treatment was higher in the pulse corticosteroid group, thus suggesting induction of lasting remission.

Other immunosuppressive drugs

Most immunosuppressive drugs used by rheumatologists as corticosteroid-sparing agents have been considered for GCA without solid evidence that the antiinflammatory activity of corticosteroids can be replaced. Azathioprine has been used with little success. Two studies have explored MTX as a corticosteroid-sparing therapy. One found possible benefit in patients managed with a combination of corticosteroid and MTX.⁵⁶ However, a double-blind, placebo-controlled trial of adjuvant MTX treatment in 98 patients with GCA failed to show an effect on control of disease activity or cumulative corticosteroid doses.⁵⁷ A phase 2 study evaluating the safety and efficacy of infliximab showed no significant benefit of blockade of tumor necrosis factor. Patients receiving corticosteroids alone or combined with relatively high doses of infliximab (5 mg/kg) had similar relapse rates and cumulative corticosteroid doses over the 22-week study period.⁵⁸ In one case series, IL-6 receptor blockade rapidly controlled systemic disease activity; however, it is unclear whether it controls the vasculitic inflammation.⁵⁹

Adjuvant therapy

Retrospective analysis of one patient cohort has suggested that low-dose aspirin reduces rates of visual loss and cerebrovascular accidents,⁶⁰ probably because of its antiplatelet action. While being maintained on chronic corticosteroid therapy, patients should be monitored for changes in bone mineral density, hypertension, and diabetes mellitus. Measures to prevent osteoporosis include calcium and vitamin D supplements and, if necessary, bone protective therapy. Patients should be encouraged to remain active. In patients with prolonged corticosteroid requirements, an exercise program is often required to prevent and manage proximal myopathy.

Fig. 156.5 Patients with biopsy-proven giant cell arteritis were treated with corticosteroids (initial dose: 1 mg/kg), and the acute-phase markers erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), and interleukin-6 (IL-6) were monitored longitudinally. With the initial high doses of corticosteroids, all three markers improved markedly. IL-6 reached the normal range (shaded blue-green area) only briefly after 90 days of therapy. With decreasing doses of corticosteroids, IL-6 and CRP returned to elevated levels, whereas ESR remained mostly within the normal range. Antineutrophil cytoplasmic antibody–associated vasculitis

■ SEBASTIAN H. UNIZONY ■ JOHN H. STONE

- Granulomatosis with polyangiitis (GPA, formerly Wegener granulomatosis) is a form of vasculitis associated with antineutrophil cytoplasmic antibodies (ANCA) directed against serine proteinase 3 (PR3). GPA is characterized by granulomatous inflammation and variable degrees of focal necrotizing vasculitis in small and medium-sized blood vessels. This disease has a tropism for the respiratory tract and kidneys. Respiratory manifestations include erosive rhinosinusitis, septal perforation, saddle nose deformity, subglottic stenosis, pulmonary nodules, and diffuse alveolar hemorrhage.
- Microscopic polyangiitis (MPA) is another form of ANCA-associated vasculitis (AAV) characterized by the presence of ANCA directed against myeloperoxidase (MPO) in the serum and focal necrotizing vasculitis of small and medium-sized blood vessels on histopathologic analysis of affected organs. MPA tends to involve the kidneys, lungs, skin, and peripheral nerves. The classic respiratory manifestation of MPA is pulmonary capillaritis, which can lead to diffuse alveolar hemorrhage.
- Eosinophilic granulomatosis with polyangiitis (EGPA, formerly Churg-Strauss syndrome) is a disease characterized by granuloma formation, tissue infiltration by eosinophils, and variable degrees of focal necrotizing vasculitis in small and medium-sized blood vessels. EGPA targets the upper and lower respiratory airways, peripheral nerves, gastrointestinal tract, and heart, and is associated with MPO-ANCA in approximately 50% of affected patients. The respiratory features of EGPA are asthma, fleeting pulmonary infiltrates, and chronic rhinosinusitis. Cardiac involvement is a major risk factor for death in EGPA.
- The most common renal manifestation of AAV is a pauci-immune focal and segmental glomerulonephritis with crescent formation (necrotizing and crescentic glomerulonephritis). This complication is seen eventually in approximately 70% to 80% of patients with GPA or MPA but in only a minority of EGPA cases (approximately 20%).
- Migratory oligoarthritis are common in AAV.
- Serious eye manifestations of AAV include necrotizing scleritis and peripheral ulcerative keratitis. These are most typical of GPA rather than MPA or EGPA. Patients with GPA can also develop inflammatory orbital pseudotumors.
- The differential diagnosis for AAV is broad and includes infectious, oncologic, and other rheumatologic diseases. EGPA must also be differentiated from other eosinophilic disorders. Histopathologic analysis remains the gold standard for the diagnosis of AAV.
- ANCA testing plays a major role in diagnosis, and positive results on ANCA assays are often helpful in suggesting the disease when presenting features are nonspecific. However, ANCA testing has limited value in monitoring disease activity and guiding therapy.
- Immunosuppressive therapy is effective in the induction of disease remissions in most cases of AAV. However, these disorders often flare during or after treatment reduction, and require therapy augmentation. Current treatments are associated with mortality and substantial morbidity.
- Glucocorticoid-dependent asthma in EGPA patients is often difficult to control with currently available therapies.

DEFINITION

The antineutrophil cytoplasmic antibody (ANCA)–associated vasculitides (AAVs) are composed of granulomatosis with polyangiitis (GPA, formerly Wegener granulomatosis), microscopic polyangiitis (MPA), and eosinophilic granulomatosis with polyangiitis (EGPA, formerly Churg-Strauss syndrome). This group of multi-organ system diseases of unknown cause shares the histopathologic features of necrotizing inflammation in small and medium-sized blood vessels, substantial overlap in the types of organs involved, and varying associations with the presence of ANCA in serum.

HISTORY

In 1866 Adolf Kussmaul and Rudolf Maier noted nodular inflammatory lesions of the medium-sized and small arteries during the autopsy of a 27-year-old journeyman tailor who had developed fever, myalgias, abdominal pain, and oliguria.¹ Their report is considered to be the first case on record of “periarteritis nodosa” (now termed *polyarteritis nodosa*, or PAN), the archetype for all forms of primary systemic vasculitis. GPA was first described by Heinz Klinger² in 1931, and 5 years later, similar findings were reported by Friedrich Wegener.³ These cases were all considered to be *grenzformen* (variants) of PAN. In 1951 EGPA was differentiated from PAN by Jacob Churg and Lotte Strauss.⁴ In contrast, MPA was not separated widely from PAN until 1994, when its tropism for small blood vessels and its tendency to cause glomerulonephritis and pulmonary capillaritis, neither of which is typical of PAN, were emphasized.⁵ Validation of the pathologic links between these diseases became clearer with the discovery of ANCA in the 1980s and the finding that most patients with GPA, MPA, and (to a lesser extent) EGPA have these autoantibodies in their blood.

EPIDEMIOLOGY

Ethnic and geographic variations have been described in the AAVs. In the United States and northern Europe, GPA is approximately twice as common as MPA, but in Japan, China, and the south of Spain, the converse is true.⁶ Large cohort studies demonstrate a predilection for white populations, and whites account for more than 90% of all AAV cases.⁷⁻⁹

Except for a possible female predominance in cases of limited GPA,¹⁰ no sex-specific risk has been clearly demonstrated in these disorders. In terms of age, AAVs have been described from childhood to old age, but the onset of GPA and EGPA peaks in the fifth decade of life and the mean age for the presentation of MPA is somewhat older, in the range of 65 to 75 years. Population-based studies in the last decade have reported incidences of 6.5 to 11 per million for GPA, 3 to 15 per million for MPA, and 0.15 to 3 per million for EGPA. Improved survival has increased the estimated prevalences of these disorders, which now range between 65 and 160 per million for GPA, 39 and 94 per million for MPA, and 11 and 46 per million for EGPA.⁶

CLINICAL FEATURES

Pattern of onset

Common individual organ manifestations of the AAVs are depicted in [Fig. 157.1](#). The onset of GPA and MPA may be insidious, acute, or even fulminant. Substantial overlap of clinical features (including ANCA positivity) sometimes makes the distinction between these entities challenging, but the

Fig. 157.1 Characteristic organ system involvement in eosinophilic granulomatosis with polyangiitis (EGPA), granulomatosis with polyangiitis (GPA), and microscopic polyangiitis (MPA). ANCA, antineutrophil cytoplasmic antibody; c-ANCA, ANCA with a cytoplasmic staining pattern; CNS, central nervous system; LCV, leukocytoclastic vasculitis; MPO, myeloperoxidase; p-ANCA, ANCA with a perinuclear staining pattern; PR3, proteinase 3. (Redrawn from Hoffman GS, Weyand C, editors. *Inflammatory diseases of blood vessels*. New York: Marcel Dekker; 2002, with permission.)

appearance of classic syndromes often allows rapid diagnoses. Thus the constellation of persistent bloody rhinorrhea, pulmonary nodules, and glomerulonephritis suggests GPA, whereas an acute pulmonary-renal disease with absent ear, nose, and throat (ENT) manifestations makes MPA more likely. When insidious in onset, GPA and MPA may evolve into an immediate threat to either the patient's life or the function of a vital organ after months or years of smoldering symptoms (e.g., upper respiratory tract disease in GPA).

The classic presentation of EGPA is a three-stage unfolding: a prodrome of rhinosinusitis and asthma, followed by a second period of blood and tissue eosinophilia (e.g., eosinophilic pneumonia), and finally a third phase dominated by vasculitis.¹¹ The latency between the prodromal phase and the overt angitis can be as long as several years. Some patients do not follow this clear-cut stepwise progression and have allergic, eosinophilic, and vasculitic symptoms in different orders or all together.

Upper respiratory tract and ears

Granulomatosis with polyangiitis and microscopic polyangiitis

Nasal, sinus, oral, pharyngolaryngeal, tracheal, and/or ear abnormalities are seen in more than 90% of all GPA cases.¹² In about one quarter of MPA patients, ENT complaints arise, but these are generally mild. Sinonasal symptoms in GPA include pain, congestion, persistent purulent and/or bloody rhinorrhea, recurrent epistaxis, and nasal crusting. Inflammation may lead to mucosal erosions as well as bone and cartilage destruction resulting in septal perforation and, in many cases, nasal bridge collapse, or saddle nose deformity (Fig. 157.2 and Fig. e157.1). Painful tongue ulcerations and a characteristic gingivitis known as *strawberry gums* (Fig. 157.3) can occur in a minority of GPA patients.

Conductive, sensorineural, or mixed hearing loss may develop in GPA. Conductive hearing loss results from involvement of the middle ear cavity (e.g., granulomatous inflammation or serous otitis media) or from eustachian tube malfunction due to nasopharyngeal disease. Of poorly understood pathophysiology, inner ear disease may be associated with

sensorineural hearing loss and/or vestibular symptoms (e.g., nausea and vertigo). Rarely, the cartilaginous structures of the external ears become inflamed, mimicking relapsing polychondritis.

Subglottic stenosis resulting from tracheal inflammation and scarring is a serious complication of GPA.¹³ Subglottic involvement can present subacutely with respiratory stridor, but is often an insidious process that may manifest as hoarseness or chronic cough. With time, airway scarring can cause tracheal stenosis (Fig. e157.2) or tracheomalacia. Pulmonary function tests (flow-volume loops) may provide a useful, noninvasive means of quantifying the airway obstruction, but the most accurate method of assessing tracheal disease in GPA is by direct laryngoscopy.

Eosinophilic granulomatosis with polyangiitis

Allergic rhinosinusitis is the earliest manifestation of EGPA in up to 80% of the cases and typically precedes the vasculitic symptoms by months or years.^{11,14} Nasal polyps, when present, can cause chronic airway obstruction. As in GPA, nasal crusting and conductive hearing loss due to granulomatous middle ear inflammation may also occur in this disorder, but destructive sinonasal disease is atypical of EGPA and characteristic of GPA.

Eyes

A variety of ocular manifestations are more likely to occur in GPA than in other AAVs. Necrotizing scleritis, which causes eye pain and conjunctival injection (Fig. e157.3), may lead to scleromalacia perforans and blindness. Peripheral ulcerative keratitis may also threaten the vision of patients if the progression to perforation ("corneal melt") is not halted by prompt treatment.¹⁵ Other ocular manifestations include conjunctivitis, episcleritis, keratitis, uveitis, retinitis, optic neuritis, and occasionally occlusion of the retinal vessels.

Retrobulbar inflammatory lesions are observed in GPA. These orbital pseudotumors may cause proptosis, ocular pain, diplopia, or vision loss due to optic nerve compression or interference with the optic nerve blood supply (Fig. 157.4). GPA patients may also develop epiphora secondary to nasolacrimal duct obstruction.

(b) CT image for a patient with longstanding GPA showing nasal septal deviation, destruction of the medial walls of the right maxillary sinus, opacification of both sinuses (arrows), and neo-ossification of all maxillary bony structures due to chronic inflammation.

Fig. 157.3 Oral manifestations of granulomatosis with polyangiitis. "Strawberry gums" due to gingival inflammation.

Lungs

Granulomatosis with polyangiitis and microscopic polyangiitis

Patients with either GPA or MPA may have pleuroparenchymal lung involvement causing cough, dyspnea, hemoptysis, and/or pleuritic chest pain. The pulmonary manifestations of GPA range from asymptomatic lung nodules

Fig. 157.4 Computed tomographic image for a patient with granulomatosis with polyangiitis showing a left orbital mass.

Fig. 157.5 Computed tomographic image of the chest for a patient with granulomatosis with polyangiitis. Multiple bilateral pulmonary nodules can be seen, many of which have cavitated.

and pulmonary infiltrates to fulminant pulmonary bleeding (see later). The pulmonary nodules (Fig. 157.5) are usually multiple and bilateral and may cavitate, raising concern for malignancy and mycobacterial and fungal infection. Radiographic infiltrates, which may wax and wane, are often initially misdiagnosed as pneumonia.

In about 10% to 15% of MPA and GPA patients, capillaritis leads to diffuse alveolar hemorrhage (DAH),⁸ a life-threatening complication characterized by hemoptysis, falling hematocrit, rapidly changing alveolar infiltrates, and acute respiratory failure (Fig. 157.6). DAH must be differentiated from other causes of hemoptysis (e.g., bronchial artery erosion by a lung nodule).

In GPA, large-airway inflammation and scarring can lead to bronchial stenosis and/or bronchomalacia. In this scenario, respiratory symptoms may become refractory to medical treatment, and recurrent postobstructive pneumonias can occur. Other possible lung manifestations are pleurisy, interstitial lung disease (associated with ANCAs against myeloperoxidase [MPO] rather than ANCAs against proteinase 3 [PR3]),¹⁶ pulmonary arterial hypertension, and pulmonary embolism.¹⁷

Eosinophilic granulomatosis with polyangiitis

Asthma is the hallmark of EGPA and is seen in more than 95% of cases.¹⁴ Obstructive airway disease usually persists over time and often becomes difficult to treat. The long latencies observed between the onset of asthma and the development of angitis are explained in part by the fact that corticosteroids, often used to treat refractory or relapsing bronchospasm, may

Fig. 157.6 Chest radiograph showing extensive air space infiltrates corresponding to diffuse alveolar hemorrhage in a patient with antineutrophil cytoplasmic antibody-associated vasculitis.

delay or mask the early stages of vascular inflammation. The putative link between some asthma treatments (e.g., leukotriene modifiers) and EGPA probably reflects the fact that effective inhaled therapies for asthma permit corticosteroid tapering, which opens the way for the emergence of more ominous inflammatory disease.¹⁸

As a result of either tissue eosinophilia or vasculitis, nearly half of EGPA patients develop transient patchy alveolar infiltrates. Bronchoalveolar lavage in these cases reveals increased eosinophil counts. Less frequently, eosinophil-rich pleural effusions, noncavitary nodules, and DAH also occur.^{19,20}

Kidneys

Nearly 80% of patients with GPA and MPA and approximately 20% of those with EGPA develop renal disease at some point during the course of their disease.^{8,12,14} Kidney involvement is a major source of morbidity in GPA/MPA but tends to be milder in EGPA. The most feared clinical presentation is a rapidly progressive glomerulonephritis (RPGN) that manifests as proteinuria (usually nonnephrotic), dysmorphic hematuria, urine cellular casts, and rapidly rising serum creatinine level. The histologic correlate of RPGN is a necrotizing, focal and segmental glomerulonephritis with crescent formation (see later section on **pathologic features**). Without appropriate therapy, this lesion may lead to irreversible loss of renal function within days to weeks. Thus the appearance of an active urine sediment or the deterioration of renal function in AAV patients signals the need for prompt workup and aggressive treatment.

Other less common renal manifestations include nephritic and nephrotic syndromes, tubulointerstitial nephritis, and slowly progressive chronic kidney disease. An isolated form of crescentic glomerulonephritis, often associated with perinuclear ANCA (p-ANCA) or MPO-ANCA, has traditionally received the name of *renal-limited vasculitis*.²¹ Some authors consider this entity to represent a forme fruste of MPA.

Musculoskeletal system

More than half of patients with AAV have prominent musculoskeletal symptoms. Arthralgias are more frequently reported, but true synovitis with joint effusions may occur. The typical pattern of involvement is migratory and oligoarticular, and large joints tend to be affected. Myalgias are common, but true myositis is very rare.

Skin

Approximately half of AAV patients develop cutaneous manifestations, and palpable purpura is the usual presentation (approximately 50%). In both GPA and EGPA, erythematous cutaneous nodules with or without

superficial crusting may occur on the scalp, elbows, hands, and feet (termed *cutaneous extravascular necrotizing granulomas* or *Churg-Strauss granulomas*; Fig. e157.4). Other dermatologic lesions include subcutaneous nodules, skin ulcers, subungual splinter hemorrhages, digital gangrene, livedo reticularis, and, mainly in EGPA, urticarial rash.^{8,12,22} The cutaneous vasculitis of AAV is nearly always less diffuse than that of immune complex-mediated conditions, such as mixed cryoglobulinemia. However, small dots of purpura in AAV may herald the development of more dangerous disease in other organs.

Nervous system

EGPA targets the peripheral nervous system (PNS) in 70% to 80% of the cases, more frequently than in MPA or GPA (15% to 60% of cases).^{8,11,14,19,20,23} Sudden-onset weakness (e.g., of the foot), paresthesias, or neuropathic pain may represent the initiation of mononeuritis multiplex or, less frequently, a distal symmetric (purely sensory or sensorimotor) polyneuropathy. Electromyography with nerve conduction study can be useful to characterize different patterns of PNS injury (e.g., mononeuropathy vs. polyneuropathy). Sural nerve biopsy, the gold standard test to demonstrate vasculitic neuropathy, commonly shows axonal degeneration. However, more specific findings such as necrotizing vasculitis of the vasa nervorum, granulomas, and/or perineural infiltration by eosinophil are seen in only half of the cases.

Central nervous system (CNS) manifestations are comparatively less common than PNS disease. CNS complications include cranial neuropathies, CNS vasculitis leading to stroke or brain hemorrhage,²⁴ and, in patients with GPA, intraparenchymal mass lesions and pachymeningitis. All three forms of AAV can infrequently present with prominent headaches and necrotizing vasculitis of the temporal arteries, mimicking giant cell arteritis.

Heart

Pericarditis, valvular lesions, and coronary vasculitis may occasionally be seen in patients with GPA and MPA. In contrast, cardiac involvement is far more common in EGPA (approximately 50%), and represents a leading cause of death.^{11,25} By mechanisms that include vasculitis, coronary vasospasm, tissue eosinophilic and/or granulomatous infiltration, and the (fibrotic) end result of those processes, patients with EGPA may develop acute coronary syndromes, myocarditis, pericarditis, valvulopathy, and endomyocardial fibrosis. Restrictive and dilated cardiomyopathy (sometimes rapidly evolving to heart failure), conduction and rhythm disturbances, and sudden cardiac arrest can arise. In addition to common cardiac testing (e.g., electrocardiography, echocardiography, coronary angiography), advanced heart imaging such as cardiac magnetic resonance and positron emission tomography might be of particular diagnostic utility in this setting.^{26,27} Heart biopsy is performed only rarely, when noninvasive tools fail to provide an accurate diagnosis.

Gastrointestinal tract

Vasculitis seldom affects the gastrointestinal (GI) system in GPA. However, mesenteric angiitis, potentially leading to ischemia-induced bowel perforation, can be seen in up to 20% to 40% of EGPA and MPA patients.^{8,14} GI manifestations include abdominal pain, nausea, vomiting, enterorrhagia, diarrhea, and intestinal occlusion. Mild transaminase elevation is detected in some cases.

Eosinophilic infiltration can affect the GI wall at different levels in EGPA, causing a variety of problems. In the lower tract, serosal disease may produce peritonitis with eosinophil-rich ascites; muscular or submucosal infiltrates can lead to dysmotility or obstructive nodular masses; and mucosal inflammation may result in bleeding. When EGPA involves the esophagus and stomach, it can cause odynophagia, dysphagia, vomiting, chest pain, and dyspepsia. Finally, pancreatitis, acalculous cholecystitis, appendicitis, and granulomatous or eosinophilic hepatitis have occasionally been reported.

Angiography lacks sensitivity to detect aneurysms and stenosis of the mesenteric circulation in AAV.⁸ Therefore, when GI tract compromise is suspected in these patients, endoscopic procedures may be used to identify mucosal ischemic changes, and mucosal-submucosal biopsy may show the presence of characteristic lesions (e.g., vasculitis, granulomas, or eosinophilic infiltration).

Blood

Several nonspecific abnormalities found on routine analysis of the peripheral blood are surrogates of an underlying inflammatory process in AAV

Fig. e157.4 Cutaneous extravascular necrotizing granulomas (Churg-Strauss granulomas) over the extensor surface of the olecranon region.

Fig. 157.7 Renal histopathologic features in antineutrophil cytoplasmic antibody-associated vasculitis (AAV). A segmental necrotizing glomerulonephritis with crescent formation is the classic kidney lesion in AAV. Immunofluorescence studies in these diseases show a paucity of immunoglobulin and complement deposition.

patients. The erythrocyte sedimentation rate and C-reactive protein level are often elevated during disease activity. The complete blood count may demonstrate mild to moderate degrees of normocytic anemia and thrombocytosis, which occasionally can be striking. The white blood cell (WBC) count can be normal or elevated. Whereas patients with GPA may have mildly increased eosinophil numbers, prominent hypereosinophilia (more than 10% on differential WBC count) is one of the diagnostic criteria for EGPA. Of note, eosinophil counts reflect disease activity in EGPA and tend to decline with adequate treatment (e.g., glucocorticoid therapy). Finally, in correspondence with a type 2 helper T-cell (Th2) polarization, the serum immunoglobulin E levels are frequently elevated in EGPA.

Other manifestations

Constitutional symptoms such as fatigue, fever, and weight loss, common in AAV, often serve as indicators of an underlying inflammatory process. These symptoms, however, rarely occur in isolation. On the other hand, granulomatous inflammation can cause pseudotumors in GPA and EGPA. These lesions may be found in potentially every organ, including the heart, parotid gland, GI tract, breast, bone, and genitourinary organs, and when they are present, the exclusion of comorbid processes (e.g., malignancy) is imperative.

PATHOLOGIC FEATURES

The discovery of ANCA (see later) has facilitated the identification of AAV. Nevertheless, in the majority of cases, a definitive diagnosis relies on the adequate interpretation of biopsy specimens. All too often, by the time clinicians recognize the pattern of organ dysfunction as suggestive of AAV and perform appropriate tissue sampling, substantial damage has already occurred.

The typical renal lesion of GPA, MPA, and EGPA is a necrotizing, focal and segmental glomerulonephritis accompanied by crescent formation (Fig. 157.7). Immunofluorescence studies of renal biopsy specimens demonstrate scant or complete absence of immunoglobulin and complement deposition, hence the term *pauci-immune glomerulonephritis*.²⁸ In GPA and EGPA, the finding of granulomatous inflammation in renal biopsy specimens is unusual.

Larger biopsy specimens from the lungs obtained by open or thoracoscopic procedures may capture the entire histologic spectrum of AAV. Pulmonary vasculitis in GPA may involve arteries, veins, and capillaries, with or without granulomatous features.²⁹ Vascular necrosis begins as clusters of neutrophils within the blood vessel wall, which degenerate and become surrounded by histiocytes. This neutrophilic debris coalesces into irregularly bordered microabscesses that, when extensive, are referred to as *geographic necrosis* (Fig. 157.8a). Well-formed granulomas contain CD4 T cells, macrophages, scattered neutrophils, multinucleated giant cells, and B cells (see Fig. 157.8b). The range of granulomatous inflammation includes either palisading or poorly formed granulomas. Of note, the vasculitic and granulomatous features of GPA may not always coexist in the same area.

In patients with MPA, which typically presents as DAH, lung biopsy often demonstrates pauci-immune vasculitis with fibrinoid necrosis of the interalveolar septal capillaries (pulmonary capillaritis) (Fig. 157.9). In contrast with lesions in the lung parenchyma, upper respiratory tract lesions in GPA

Fig. 157.8 Pulmonary histopathologic features in granulomatosis with polyangiitis. (a) Extensive coalescent areas of necrosis in a biopsy specimen from a pulmonary nodule. This pathologic finding is termed *geographic necrosis*. (b) Numerous multinucleated giant cells surrounding an ovoid region of necrobiosis.

Fig. 157.9 Pulmonary histopathologic features in microscopic polyangiitis. There is abundant extravasation of red blood cells into the alveolar space. Inflammatory cells infiltrate the wall of the capillary vessels and the interstitial space of the alveolar septa.

Fig. 157.10 Histopathologic features of eosinophilic granulomatosis with polyangiitis (EGPA). Small-vessel vasculitis with marked angiocentric infiltrates of eosinophils in a patient with EGPA.

frequently have a nondiagnostic histologic appearance, showing only signs of unspecific acute and chronic inflammation.³⁰

The anatomic-pathologic hallmarks of EGPA are necrotizing angitis of small and medium-sized blood vessels, extravascular necrotizing granulomas, and tissue eosinophilic infiltration (Fig. 157.10).^{11,31} These lesions may occur in isolation or coexist. As in GPA, vasculitis in EGPA can display granulomatous or nongranulomatous features and involve arteries, capillaries, and veins. A perivascular cuff of eosinophils may be present as well, and eosinophil-rich granulomas tend to locate near to the small vasculature. A less specific interstitial infiltrate of eosinophils may be present within the

BOX 157.1 CLINICAL UTILITY OF ANTINEUTROPHIL CYTOPLASMIC ANTIBODY (ANCA) TESTING

- Combined testing using immunofluorescence (IF) assays and enzyme immunoassays (EIAs) for antibodies to proteinase 3 (PR3) or myeloperoxidase (MPO) is recommended. The most reliable results are positivity for ANCAs by both IF and EIA. However, positive serologic test results alone are not diagnostic of ANCA-associated vasculitis (AAV).
- Even with rigorous serologic evaluations, not all patients with AAV test positive for ANCAs. ANCAs are seen in 90% to 95% of individuals with generalized granulomatosis with polyangiitis (GPA), 70% to 80% of those with limited GPA forms, 70% of those with microscopic polyangiitis, 40% to 50% of those with eosinophilic granulomatosis with polyangiitis, and 70% to 80% of patients with renal-limited vasculitis.
- A host of systemic illnesses (which may mimic AAV), including infections, malignancies, and systemic rheumatic conditions, may be associated with the presence of ANCAs.
- Although the sensitivities of the two testing techniques are comparable, EIA has a higher specificity than IF.
- Even in patients who are ANCA positive, the titers are unreliable indicators of disease activity. As a rule, predicating treatment decisions on ANCA titers is a mistake.
- The direct role of ANCAs in the pathogenesis of human AAV remains unclear. Most current evidence suggests that ANCAs may be one of the effector pathways of tissue injury in these disorders, because ANCAs enhance the degranulation of cytokine-primed neutrophils *in vitro*, and anti-MPO and anti-PR3 antibodies trigger the development of crescentic glomerulonephritis and pulmonary capillaritis in animal models.

lungs or occupy extrapulmonary sites including the heart, upper airway, skin, GI tract, kidneys, and peripheral nerves.^{11,19,31}

When AAV involve the small blood vessels of the skin dermis, biopsy specimens reveal leukocytoclastic vasculitis. Cutaneous extravascular necrotizing granulomas with or without eosinophil predominance may also occur in EGPA and GPA, respectively.

ANTINEUTROPHIL CYTOPLASMIC ANTIBODIES

ANCAs are autoantibodies directed against MPO, PR3, or other constituents (e.g., the LAMP-2 protein) of the primary granules of neutrophils and monocyte lysosomes. Since their discovery in 1982,³² ANCA testing has become an essential part of the diagnostic evaluation of patients with small-vessel vasculitis.³³ Two types of assays for these antibodies, immunofluorescence (IF) and enzyme immunoassay (EIA), are now in common use. The current role of ANCA testing in the diagnosis and management of AAV is summarized in Box 157.1.

Different factors contribute to the variation in sensitivity, specificity, and positive and negative predictive value of ANCA testing. These determinants include the method of detection used, the vasculitis type (i.e., GPA, MPA, or EGPA) and extension (e.g., limited vs. generalized GPA), and the disease activity at the time of sampling. With IF, three principal patterns of fluorescence are recognized: cytoplasmic (c-ANCA), perinuclear (p-ANCA), and atypical (x-ANCA) (Fig. 157.11). In patients with vasculitis, the c-ANCA pattern usually corresponds to the presence of anti-PR3 antibodies (PR3-ANCA) and the p-ANCA pattern typically correlates with anti-MPO antibodies (MPO-ANCA), which can be detected by EIA.

When IF and EIA results are considered together, ANCAs are seen in approximately 90% to 95% of generalized GPA cases during active disease, and in around 70% to 80% of cases of the limited forms.³⁴ Although a negative ANCA test result does not preclude the diagnosis of GPA, the detection of a c-ANCA pattern on IF in combination with PR3-ANCA detection by EIA strongly suggests this disorder. In contrast, the p-ANCA/MPO-ANCA combination is more prevalent in MPA (70% of cases), EGPA (40% to 50%), and renal-limited vasculitis (70% to 80%); however, it also occurs in a minority of GPA patients (approximately 10%). Of note, it has been suggested that the presence of ANCAs in EGPA^{19,20,31} is associated with vasculitic manifestations (e.g., glomerulonephritis, peripheral neuropathy, palpable purpura, DAH), whereas ANCA-negative cases more often tend to develop eosinophilic features (e.g., cardiomyopathy).

Atypical ANCA patterns are found in a wide variety of disorders, such as inflammatory bowel disease, systemic immune-mediated diseases, and infections.³³ These atypical patterns are sometimes difficult to distinguish from the p-ANCA pattern. Thus, regardless of the pattern revealed by IF,

Fig. 157.11 Antineutrophil cytoplasmic antibodies (ANCAs) demonstrated by immunofluorescence. (a) Cytoplasmic pattern (c-ANCA). (b) Perinuclear pattern (p-ANCA).

positive results on IF assays should be confirmed by EIAs, which also determine the specific antigen targeted by the ANCA (e.g., PR3, MPO).

In general, ANCA levels have correlated imperfectly with disease activity.³⁵ Titers of antibodies tend to decline following the institution of immunosuppressive therapy, but approximately half of patients who achieve complete clinical remission remain ANCA positive to some degree, albeit usually with a much lower titer than at the start of treatment. The period between the rise in ANCA titers and the appearance of renewed disease activity may be up to several years. Thus ANCA titers are poor predictors of the timing of disease flares, and in a significant minority of cases the direction of serial ANCA titers is misleading, with disease flares occurring in the absence of a rise or even in the setting of declining ANCA titers. Thus, for most patients, treatment should not be guided by ANCA titers in the absence of clinically evident disease.

Despite advances in ANCA testing techniques, the cornerstone of diagnosis in AAV remains the combination of typical clinical features and histopathologic findings. When the diagnosis is uncertain, all reasonable avenues should be pursued to obtain biopsy specimens to confirm the diagnosis.

DIFFERENTIAL DIAGNOSIS

The histologic distinction between GPA, MPA and EGPA can often be challenging. Renal features of AAV are frequently indistinguishable, and in

TABLE 157.1

Nomenclature and classification criteria for antineutrophil cytoplasmic antibody–associated vasculitides

Chapel Hill Consensus Conference nomenclature*	
Granulomatosis with polyangiitis (formerly Wegener granulomatosis)	Granulomatous inflammation involving the respiratory tract and necrotizing vasculitis affecting small to medium-sized vessels (e.g., capillaries, venules, arterioles, and arteries). <i>Necrotizing glomerulonephritis is common.</i>
Microscopic polyangiitis	Necrotizing vasculitis, with few or no immune deposits, affecting small vessels (i.e., capillaries, venules, or arterioles). <i>Necrotizing arteritis involving small and medium-sized arteries may be present. Necrotizing glomerulonephritis is very common. Pulmonary capillaritis often occurs.</i>
Eosinophilic granulomatosis with polyangiitis (formerly Churg-Strauss syndrome)	Eosinophil-rich and granulomatous inflammation involving the respiratory tract, and necrotizing vasculitis affecting small to medium-sized vessels and associated with asthma and eosinophilia.
1990 American College of Rheumatology classification criteria for granulomatosis with polyangiitis and eosinophilic granulomatosis with polyangiitis †	
Granulomatosis with polyangiitis	Eosinophilic granulomatosis with polyangiitis
1. Nasal or oral inflammation Painful or painless oral ulcers, or purulent or bloody nasal discharge	1. Asthma History of wheezing or diffuse high-pitch rales on expiration
2. Abnormal chest radiograph Nodules, fixed infiltrates, or cavities	2. Eosinophilia Eosinophilia of >10% eosinophils on white blood cell differential count
3. Urinary sediment Microhematuria or red cell casts	3. Mononeuropathy or polyneuropathy Development of mononeuropathy, multiple mononeuropathies, or polyneuropathy (i.e., glove/stocking distribution) attributable to systemic vasculitis
4. Granulomatous inflammation on biopsy specimen Granulomatous inflammation within the wall of an artery or in the perivascular area	4. Pulmonary infiltrates, nonfixed Migratory or transitory pulmonary infiltrates on radiographs (not including fixed infiltrates) attributable to systemic vasculitis
	5. Paranasal sinus abnormality History of acute or chronic paranasal sinus pain or tenderness or radiographic opacification of the paranasal sinuses
	6. Extravascular eosinophils Biopsy including artery, arteriole, or venule showing accumulations of eosinophils in extravascular areas

addition, all these patients may develop musculoskeletal symptoms, peripheral neuropathy, skin manifestations, and the life-threatening complication of alveolar hemorrhage.

Typical features of GPA, MPA and EGPA are contrasted in Fig. 157.1, and the classification criteria for the AAVs are shown in Table 157.1. GPA can be differentiated from MPA essentially by the presence of conspicuous upper respiratory tract symptoms, the finding of granulomas as part of the histologic lesion, and its strong association with c-ANCA/PR3-ANCA. Although EGPA is also a granulomatous disease that affects the upper airway, virtually all EGPA patients have asthma and significant hypereosinophilia (both absent in GPA and MPA). Furthermore, whereas biopsy specimens from patients with GPA sometimes demonstrate a mild degree of eosinophil infiltration, striking tissue eosinophilia is highly characteristic of EGPA. Finally, unlike GPA, EGPA does not usually cause destructive upper airway disease or cavitary pulmonary nodules and tends to affect the heart, peripheral nerves, and GI tract more often.

More important in terms of treatment implications is distinguishing AAVs from a myriad of disorders of varied etiologies that can mimic GPA, MPA, or EGPA. Other forms of vasculitis presenting with skin lesions (e.g., palpable purpura), arthralgias, and/or glomerulonephritis should be considered. In this regard, Henoch-Schönlein purpura, cryoglobulinemia, and systemic rheumatoid vasculitis or systemic lupus erythematosus (SLE) can at times be misleading. However, each one of these rheumatic diseases may have other clinical manifestations (e.g., malar rash, erosive synovitis), laboratory findings (e.g., circulating cryoglobulins, anti-cyclic citrullinated protein antibodies, antinuclear antibodies), and pathologic features (e.g., immune deposits on tissue biopsy specimens) that shift the balance during the differential process.

AAVs must be distinguished from pulmonary-renal syndromes such as anti-glomerular basement membrane (anti-GBM) disease, immune complex-mediated disorders, sepsis with disseminated intravascular coagulation, and others. In anti-GBM disease, the relevant antibodies can be

measured in the blood or observed as linear staining in indirect IF studies of lung or kidney tissue. Patients with SLE and most other immune complex-associated diseases have hypocomplementemia, specific serologic markers (e.g., double-stranded DNA antibodies), and a characteristic granular IF staining pattern on renal biopsy specimens.

Immunoglobulin G4–related disease can mimic both GPA and EGPA closely in its tendency to form mass lesions, its ability to affect many of the same organs (particularly the orbital region, lungs, and kidney), and its common association with mild to moderate eosinophilia. Levamisole, an adulterant commonly used in cocaine, can induce a vasculitic condition associated with a variety of autoantibodies, including ANCAs, antiphospholipid antibodies, and others, leading to diagnostic confusion.

GPA limited to the respiratory tract may pose a difficult diagnostic problem. Infection (mycobacterial or fungal infection, actinomycosis, syphilis), malignancy (squamous cell carcinoma, extranodal T-cell lymphoma), or illicit drug use (intranasal cocaine) can present with destructive ENT lesions. Because granulomatous infections of the lung (e.g., with mycobacteria or fungi) may also cause vasculitis and necrosis, a diagnosis of GPA should not be rendered based on lung biopsy specimens until special stains and cultures have yielded negative results. Lymphomatoid granulomatosis, an angiocentric immunoproliferative disorder, may be difficult to differentiate from GPA (and certain chronic infections like tuberculosis) because it can present with constitutional symptoms, lung nodules, and a polymorphic inflammatory infiltrate associated with tissue necrosis.

Finally, hypereosinophilia and a marked association with atopic manifestations bring up a particular group of differential diagnoses that are pertinent to consider when EGPA is suspected. Obstructive lung disease in the presence of fleeting pulmonary infiltrates and other classic organ manifestations (e.g., mononeuritis multiplex) make straightforward the distinction of EGPA from uncomplicated asthma or allergic rhinosinusitis; however, long latencies between different EGPA phases can sometimes delay a definite diagnosis considerably. Conditions associated with blood and/or tissue

eosinophilia such as drug reactions, parasitic infections, allergic bronchopulmonary aspergillosis, eosinophilic pneumonia, and eosinophilic esophagogastritis may at times enter the differential diagnosis of EGPA. Unlike EGPA, these problems are not characterized by granulomatous inflammation. Moreover, although the histologic findings in eosinophilic pneumonia and eosinophilic esophagogastritis may be indistinguishable from those in EGPA, these organ-restricted eosinophilic disorders are not systemic and remain confined to the respiratory and GI tract, respectively. Finally, idiopathic hypereosinophilic syndrome may be particularly difficult to differentiate from EGPA, and some cases meet criteria for both disorders. Clues to separate these entities are the virtual absence of asthma in idiopathic hypereosinophilic syndrome and the presence of vasculitis and/or granulomas in EGPA.

ETIOLOGY AND PATHOGENESIS

Environmental influences are thought to interplay with genetic and epigenetic factors in the origination of AAVs, but the ultimate cause of these disorders remains elusive. The striking white predominance in AAVs indicates that genes probably play an important role. However, the rare occurrence of familial cases suggests that heritable factors alone are not sufficient. A genomewide association study of GPA and MPA patients showed major histocompatibility complex (MHC) and non-MHC associations. PR3-ANCA polyangiitis (mostly GPA) was associated with single-nucleotide polymorphisms at the HLA-DPB1 (confirming prior studies), SERPINA1 (α_1 -antitrypsin), and PRTN3 loci, whereas an association with HLA-DQ was observed in MPO-ANCA vasculitis (mostly MPA).³⁶ Fine mapping and functional studies are required to define the specific roles of these genetic variants. Candidate gene studies have reported susceptibility polymorphisms associated with HLA-DR, interleukin-10 (IL-10), CTLA-4, CD226, CD18, PTPN22, and Fc γ receptor genes, but many of these associations need further research.^{37,38}

Environmental exposures represent other potential etiologic factors in AAV. Inhaled materials (e.g., silica) can induce a delayed-type hypersensitivity reaction and therefore may play a role in GPA. Different triggers including allergens and drugs (e.g., leukotriene receptor antagonists, omalizumab, antithyroid agents, levamisole) have been linked to the initiation of EGPA and MPA.^{39,40} Moreover, since the original descriptions of GPA by Klinger² and Wegener,³ microbial pathogens have been considered as possible precipitants of this disease, and *Staphylococcus aureus* has been implicated as the cause of an autoimmune response against PR3.⁴¹

Regardless of the initiating event(s), three main pathogenic mechanisms can be recognized within the complex network of adaptive and innate immune cells involved in the pathophysiology of AAV (Fig. 157.12). First, neutrophils, macrophages, dendritic cells, and T and B lymphocytes have different roles in the process of *vasculitic damage* (e.g., crescentic glomerulonephritis) in GPA, MPA, and EGPA. Second, in GPA (and less prominently in EGPA), there is tissue disruption by invasive *granulomatous inflammation* (e.g., orbital pseudotumor, lung nodules). Third, *eosinophil-mediated injury* is regarded as a prominent effector pathway in EGPA (e.g., eosinophilic myocarditis). In this setting, cytokines (e.g., tumor necrosis factor- α [TNF- α], IL-17, interferon- γ [IFN- γ], IL-5), chemokines (e.g., IL-8, eotaxin-3, CCL17), components of the complement cascade, and ANCAs themselves (see later), orchestrate and amplify different aspects of the inflammatory response. A schematic representation of the proposed molecular events involved in GPA, MPA, and EGPA is shown in Fig. 157.12.

The cellular branch of the adaptive immune system, fundamental for the origination of autoimmunity, also contributes to the perpetuation of the self-reacting process and provides additional effectors of tissue damage. Changes in the composition and activation status of the CD4 T-cell subsets have been described in AAV.⁴² Whereas a Th17 response appears to contribute to this group of diseases in general, GPA and MPA also feature the upregulation of the Th1 axis (TNF- α , IFN- γ),⁴³ and a Th2 polarization (IL-4, IL-5, IL-13) has been demonstrated primarily in EGPA.⁴⁴ More recently, numerical reduction and/or functional defects in the regulatory T-cell compartment have been reported in AAV as well.⁴²

Clinical trials of B-cell depletion have provided the most conclusive evidence for a pathogenic role of B cells in AAV.^{45,46} Besides differentiating into ANCA-producing plasmocytes, B cells have an extended spectrum of antibody-independent actions that include regulatory and antigen-presenting functions and the expression of costimulatory molecules and soluble mediators that can modulate effector T-cell responses and maintain T-cell memory.

PR3 and MPO are enzymes expressed in the leukocyte granules that can shuttle to the cytoplasmic membrane upon cellular activation. Experimental evidence suggests that ANCA activation of primed neutrophils in the

microcirculation may be an important common effector mechanism in AAV.⁴⁷ Neutrophils of patients with GPA have higher expression of membrane-bound PR3 than healthy controls,⁴⁸ and this phenomenon is increased during disease relapse.⁴⁹ *In vitro*, ANCAs can induce cytokine-stimulated neutrophils not only to degranulate and produce reactive oxygen species⁵⁰ but also to adhere to and damage bystander endothelial cells.^{51,52} *In vivo*, passive transfer of MPO⁵³ and PR3⁵⁴ autoantibodies can trigger crescentic glomerulonephritis and pulmonary capillaritis in animal models, and one case of transplacental passage of ANCAs followed by neonatal pulmonary-renal syndrome has been reported.⁵⁵ Of note, ANCA-stimulated neutrophils become a source of proinflammatory mediators⁵⁶ and also release neutrophil extracellular traps (NETs).⁵⁷ Neutrophil-derived IL-6, IL-23, and IL-17 may stimulate B and T cells, therefore integrating the innate and adaptive systems.⁵⁸ NETs, on the other hand, are chromatin-rich structures that also contain the PR3 and MPO. It is hypothesized that in AAV, increased neutrophil NET formation (“NETosis”) could fuel the immune system with autoantigens and also stimulate B lymphocytes and dendritic cells in a Toll-like receptor 9-dependent manner.

Because patients are normocomplementemic and the end-organ damage is pauci-immune, the participation of the complement cascade was not suspected in AAV until recently. Complement depletion, genetic ablation of specific proteins (factor B, factor C5 and C5a receptor), and pharmacologic inhibition of C5 signaling have been shown to protect animals from a challenge with anti-MPO antibodies.⁵⁹⁻⁶¹ Human neutrophils bridged by ANCAs are able to activate the alternative complement pathway on their surfaces, possibly through the release of properdin or reactive oxygen species.^{60,62} The anaphylatoxin C5a generated by this mechanism is a potent inflammatory molecule that not only amplifies the process by targeting other cells (e.g., endothelium) but also chemoattracts and furthers primes other neutrophils, which upregulate their membrane expression of MPO and PR3 antigens; therefore a vicious cycle is created.^{60,63}

Granulomatous inflammation, the hallmark of GPA, is a cell-mediated immune reaction. PR3 has been shown to induce maturation of dendritic cells and endow them with the capacity to shape a Th1 response.⁶⁴ During disease remission, effector memory CD4 T cells with natural killer–like properties are expanded in peripheral circulation. These cells, which represent an important source of IFN- γ and TNF- α , probably migrate to the target tissues during active disease and represent the driving force for monocyte accumulation, epithelioid differentiation and fusion, and granuloma formation.⁶⁵ On the other hand, granulomatous lesions in GPA could function as a (tertiary) lymphoid-like tissue in which autoreactive B cells expand, mature, and sustain the production of anti-PR3 antibodies.⁶⁶

In EGPA, endothelial and epithelial cells produce chemotactic molecules (e.g., eotaxin-3, CCL17) that regulate the trafficking of eosinophils into the foci of inflammation.^{67,68} Eosinophils are found not only in vasculitic lesions and necrotizing granulomas but also in developing interstitial infiltrates.^{4,11} The expansion of the eosinophil compartment in EGPA is considered to be modulated by cytokines produced by Th2-polarized cells (e.g., IL-4, IL-5, IL-13) with a possible contribution of the IL-23/Th17 axis. IL-5, levels of which are increased in EGPA during active disease,⁶⁹ selectively intervenes in the mobilization, maturation, and survival of eosinophils and is considered the most potent stimulator of eosinophil function. Upon homing into the target organs, eosinophils degranulate and release cytotoxic enzymes (e.g., major basic protein, eosinophil-derived neurotoxin, eosinophil cationic protein). It has been suggested that in EGPA, eosinophil-derived IL-25 is responsible for the differentiation of naive CD4 cells toward the Th2 lineage, therefore closing a cross-talk loop that could perpetuate hypereosinophilia and organ infiltration.

TREATMENT

Overview

Data from the 1950s indicate that, in the absence of appropriate treatment, patients with fully expressed GPA have a mean survival of only 5 months and 82% mortality at 1 year.⁷⁰ The prognosis of AAV is not nearly so grim in the modern era because the use of glucocorticoids and immunosuppressants has dramatically improved the short-term survival of these patients (the actual remission induction rate is 80% to 95%).^{12,45,71-73} However, decreased mortality has made evident the chronic morbidity burden associated with these disorders (see later).

Current choices for the treatment of GPA/MPA and EGPA are based on the classification of specific cases into the category of “severe, generalized disease or poor prognosis” versus “localized, early systemic disease or good prognosis.”^{74,75} Severe and generalized GPA/MPA constitute a threat to the

PROPOSED MOLECULAR EVENTS IN THE PATHOGENESIS OF AAV

Fig. 157.12 Pathogenic mechanisms in antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis (AAV). (1) Antigen-presenting cells (APCs) interact with helper CD4 T cells and B cells for the production of ANCAs. (2) The process of tolerance break may be permitted by numerical or functional defects in the regulatory T cells (Treg), which also may limit subsequent effector pathways insufficiently. (3) ANCAs cross-link Fcγ receptor (FcγR) and myeloperoxidase (MPO) or proteinase 3 (PR3) on the surface of primed neutrophils, which leads to cellular degranulation, production of reactive oxygen species (ROS), vascular endothelial damage, and tissue injury. (4) Type 17 helper T (Th17) cells promote neutrophil recruitment to the foci of inflammation and may provide additional effector mechanisms. (5) In granulomatosis with polyangiitis, Th1 cells and effector memory T cells (T_{EM}), which are an important source of tumor necrosis factor- α (TNF- α) and interferon- γ (IFN- γ), further prime neutrophils and drive the formation of granulomatous inflammation. Granulomas are composed of activated CD4 T cells, macrophages, giant cells, neutrophils, and B cells. (6) In eosinophilic granulomatosis with polyangiitis, eosinophils are recruited to the sites of inflammation, and cytokines produced by Th2 cells (e.g., interleukin-5 [IL-5]) promote their activation with degranulation of cationic proteins (e.g., major basic protein) that cause tissue damage. (7) Positive feedback and amplification loops operate in AAV at different levels, perpetuating and augmenting the self-reacting process (e.g., neutrophil extracellular nets [NETs], cytokines [IL-6, IL-23, IL-17, TNF- α , IL-25], complement factors [C5a]). TGF- β , transforming growth factor- β .

function of vital organs or to the patient's life (e.g., RPGN, DAH, intestinal ischemia, necrotizing scleritis, vasculitic neuropathy). Conversely, localized or early systemic disease does not pose such threats in the short term (e.g., ENT disease, cutaneous lesions, arthritis). A five-factor score (FFS) is used to classify EGPA patients according to the presence or absence of clinical manifestations associated with poor prognosis (creatinine level of more than 1.58 mg/dL [140 μ mol/L], proteinuria of more than 1 g protein per day, cardiomyopathy, severe GI involvement, and CNS manifestations).⁷⁵ The presence of one or more of these features reflects severe disease and warrants aggressive treatment.

Generalized and severe granulomatosis with polyangiitis and microscopic polyangiitis

The classic National Institutes of Health (NIH) treatment,¹² which consisted of 1 year of oral cyclophosphamide (CYC) (2 mg/kg daily) in combination with prednisone (1 mg/kg daily tapered over 6 to 12 months), has been modified in the last decade in an attempt to spare glucocorticoids and minimize the exposure to alkylating agents. Furthermore, controlled trials have demonstrated that CYC-based and rituximab (RTX)-based regimens have comparable efficacy for the treatment of generalized GPA and MPA.

Current CYC-based strategies consist of a short and aggressive phase of induction of remission (e.g., 3 to 6 months of CYC), followed by lower-intensity therapy with agents such as azathioprine (AZA) (CYCAZAREM trial⁷¹) or methotrexate (MTX) (WEGENT trial⁷³) to prevent disease exacerbations (maintenance of remission). Mycophenolate mofetil was found to be inferior to AZA in a randomized study (IMPROVE trial⁷²), but its use in specific settings (e.g., MPO-associated AAV) may need further investigation.^{76,77} A wide array of other therapies including intravenous immunoglobulin (IVIG), calcineurin inhibitors, and leflunomide have been employed in small numbers of patients, but so far insufficient data exist to judge their efficacy. Of note, etanercept was ineffective for the maintenance of disease remission in a placebo-controlled trial,⁷⁸ and small studies of infliximab and adalimumab did not show significant results either.

The optimal length of maintenance therapy is not clear, but continuation of immunosuppression for longer than 12 to 18 months after remission is reasonable because the majority of disease exacerbations occur after therapy discontinuation.^{71,79} The REMAIN trial designed to evaluate the safety and efficacy of long-term maintenance treatment with AZA and low-dose glucocorticoids is currently ongoing. Before the initiation of AZA therapy, testing of the individual's phenotype for the thiopurine methyltransferase (TPMT) enzyme is advised to avoid potentially serious complications.⁷¹

In clinical practice, the use of either daily oral or intermittent intravenous (IV) CYC varies from center to center. In the CYCLOPS trial,⁸⁰ which compared IV pulse CYC with oral CYC, the two treatment regimens produced similar remission rates even though the group given IV CYC received half the cumulative dose of CYC of the orally treated group. Extended follow-up for a median duration of 4.3 years revealed comparable survival rates (approximately 80%) and adverse effect profiles for both approaches; however, patients treated with pulse therapy had a higher risk of relapse.⁸¹ Long-term data focused on the incidence of malignancy associated with each strategy may shift the balance toward IV or oral administration. Regardless of the route employed, induction of neutropenia is not required to achieve therapeutic effects, and meticulous monitoring of the WBC count is essential to avoid life-threatening infections. Oral CYC should be withheld temporarily and the IV dose should be adjusted if the WBC count falls below 4.0×10^9 per liter.

Since 2010, B-cell depletion strategies have emerged as a strongly preferable alternative to CYC for treatment of GPA and MPA. In two controlled studies,^{45,46} a single course of RTX demonstrated efficacy and short-term safety equivalent to that of CYC followed by AZA for remission induction and maintenance; all patients also received glucocorticoids. In the RAVE trial,⁴⁶ RTX induced disease remission at 6 months and permitted the discontinuation of prednisone in 64% of patients, compared with 53% of those given CYC. Of note, among patients with relapsing disease at baseline, RTX was more efficacious than CYC. Extended follow-up in this trial showed that at 12 months, 42% of the patients in the RTX arm and 38% of those in the CYC arm remained in remission without glucocorticoids.⁸² In the RITUXVAS study,⁴⁵ a similar percentage of patients in the RTX and CYC groups had their disease brought under control within 3 months (91%) and remained free of relapse at 12 months of follow-up (85% to 90%). Controlled studies exploring the long-term safety and efficacy of B-cell depletion as a maintenance strategy, including serial retreatment, and comparisons with oral immunosuppression (e.g., AZA) are required. Nevertheless, the RAVE data indicate that among patients newly diagnosed with either GPA or MPA, approximately 45% of patients will be in remission and not receiving glucocorticoids for longer than 1 year if treated with remission induction regimens that involve either RTX or CYC.

RTX was superior to CYC with regard to the short-term occurrence of selected adverse events such as neutropenia and had led to fewer cases of pneumonia at 18 months of follow-up in the RAVE trial. However, the combination of RTX and high-dose glucocorticoids also increases the risk of treatment-related morbidity, and patients must be followed closely. Nevertheless, RTX-based regimens are likely to be considerably safer over long-term follow-up with regard to malignancy induction, bladder toxicity, and infertility, which makes this approach the optimal current strategy for remission induction (and possibly maintenance) in most patients.

Localized and early generalized granulomatosis with polyangiitis and microscopic polyangiitis

Localized or early generalized GPA/MPA may respond to the combination of MTX and glucocorticoids.⁸³ In the NORAM trial,⁷⁹ MTX and CYC were compared for remission induction in patients with newly diagnosed disease. At 6 months, remission was achieved in approximately 90% of patients in both groups. On withdrawal of therapy after remission, however, relapse rate was significantly higher in the MTX group,⁸⁴ and many of these patients ultimately require CYC therapy. Of note, MTX should be avoided when the serum creatinine concentration is more than 2.0 mg/dL, because renal dysfunction significantly heightens the potential for myelotoxicity.

Trimethoprim-sulfamethoxazole has a limited or no role in the treatment of active localized GPA, but this antibiotic may decrease the risk of relapse.⁸⁵

Eosinophilic granulomatosis with polyangiitis

Patients with EGPA without poor prognostic factors (FFS = 0) achieve disease remission with glucocorticoids alone in more than 90% of cases. Although one third of these patients experience relapse upon glucocorticoid tapering, the long-term survival of this population is excellent.³¹ In the presence of poor prognostic factors, a regimen of 12 pulses of IV CYC is superior to 6 pulses (both in combination with glucocorticoids) in terms of disease-free survival, but no differences are seen in induction of remission, occurrence of early adverse events, major relapse rate, and 5-year mortality (approximately 10%).⁸⁶ Upon CYC discontinuation, flares are frequent in the absence of maintenance therapy (more than 70% of cases). Although high-quality data favoring a staged approach to treatment are lacking in EGPA, extrapolation of results from GPA/MPA trials suggests that a lower-intensity regimen for remission maintenance (e.g., AZA) may prevent

exacerbations and decrease the long-term adverse effects associated with prolonged CYC exposure.

In refractory and relapsing EGPA, different treatment modalities have been used with mixed results. In an attempt to spare glucocorticoids, these patients often receive AZA, MTX, mycophenolate mofetil, TNF- α antagonists, IVIG, and plasma exchange. Unfortunately, the rate of response with these approaches has been highly variable, so that any strong recommendation is inadequate. Moreover, successful treatment with RTX has been described in small series and case reports,^{87,88} but controlled studies are lacking.

Better understanding of the pathophysiology of EGPA has focused attention on Th2- and eosinophil-targeted therapies. IFN- α , a cytokine that inhibits eosinophil degranulation and the production of Th2 cytokines by CD4 cells (including IL-5), might have a role in inducing remission in refractory cases,⁸⁹ but the long-term use of this agent seems to be ineffective.⁹⁰ More recently, encouraging results were obtained with the anti-IL-5 monoclonal antibody mepolizumab in two pilot trials in patients with refractory disease. During mepolizumab therapy, blood eosinophilia declined and patients maintained disease remission while being able to taper glucocorticoid use. After drug discontinuation, relapses occurred mostly in patients in whom the eosinophil count returned to pretreatment levels, which suggests that continuous therapy might be required in some cases.^{91,92}

NONPHARMACOLOGIC INTERVENTIONS

Upper airway disease in granulomatosis with polyangiitis and eosinophilic granulomatosis with polyangiitis

In GPA, subglottic stenosis and sinonasal disease may respond incompletely to immunosuppressive therapy. Once scarring is well established in the subglottic region, airway narrowing may be secondary to the progression of fibrosis rather than to GPA-related inflammation. In such cases, surgical dilation is required for the airway stenosis. GPA often leads to chronic nasal and sinus dysfunction from damage caused by the disease itself, superinfection of devitalized tissues, and/or surgical procedures performed for either diagnosis or treatment. Regardless of disease activity, most patients require daily (or more frequent) saline irrigations to minimize the accumulation of secretions and crusts and to reduce the incidence of secondary infections. Distinguishing between worsening sinus disease caused by active GPA and that caused by superimposed infection may be difficult, and sometimes both are present simultaneously. In the absence of a prompt response to antibiotics, surgical drainage and biopsy are often required for a more definitive diagnosis. Nasal polyps develop in up to 80% of EGPA patients. A subset of these patients require polypectomy to relieve the symptoms of nasal airway obstruction.

Plasma exchange

Data demonstrating the pathogenicity of ANCA in animal models has led to the investigation of plasma exchange in human disease. Besides eliminating ANCAs, plasma exchange could theoretically exert beneficial effects in AAV by extracting cytokines and activated complement and coagulation factors from the bloodstream. In the MEPEX trial,⁹³ AAV patients with severe renal failure (creatinine concentration of more than 5.7 mg/dL) received induction therapy with glucocorticoids and CYC, and were randomly assigned either to undergo seven plasma exchange sessions or to receive three IV methylprednisolone pulses. Although the progression to end-stage renal disease (ESRD) was reduced by 24% at 12 months in the plasma exchange group, there was no survival benefit, and the initial advantage of plasma exchange in promoting renal recovery was not appreciated on long-term follow-up.⁹⁴ Although the ongoing PEXIVAS trial may definitely clarify the effects of plasma exchange on ESRD and mortality, in the meantime, plasma exchange remains an experimental therapy with potentially serious adverse effects (e.g., line-associated infections) that may be considered in patients with life-threatening complications of AAV such as severe acute renal failure and DAH that are not responding to immunosuppressive therapy.

Dialysis

The requirement for acute dialysis in AAV does not necessarily indicate irreversible loss of renal function, because more than 50% of patients with AAV who undergo acute renal replacement therapy become dialysis independent with prudent use of aggressive therapy for active disease. Recovery

of native renal function usually occurs within 2 to 3 months of initiation of dialysis. Given that ESRD and dialysis represent risk factors for infection in themselves, clinicians should remember to dose CYC appropriately in patients with lower glomerular filtration rates to avoid increasing the rate of infectious complications beyond that already seen in this population.

Renal transplantation

ESRD has been estimated to occur in up to 20% of some AAV cohorts. Although studies of AAV patients who have undergone renal transplantation are small, results to date suggest that the rates of both allograft and patient survival are similar to those in the nonvasculitic, nondiabetic transplant population. ANCA status at the time of transplantation is not a useful prognostic marker, and its presence should not preclude consideration of transplantation in a patient who is otherwise in apparent remission.⁹⁵

DISEASE ASSESSMENT

Tools used for measuring disease activity and extension in AAV include the Birmingham Vasculitis Activity Score (BVAS)⁹⁶ and its variant for GPA (BVAS/WG),⁹⁷ a physician global assessment, the Disease Extent Index (DEI), and the FFS. The BVAS is the most widely used in GPA and MPA and consists of nine groups of organ system–based items. Remission is defined in the BVAS as the absence of active disease in any organ system (BVAS = 0). Patients with EGPA are frequently classified using the FFS.⁷⁵ Long-term damage attributed to the disease and its treatment is usually measured with instruments such as the Vasculitis Damage Index (VDI) and the Combined Damage Assessment Index (CDAI).⁹⁸

MORBIDITY AND MORTALITY

Descriptions of large cohorts of GPA patients (the longitudinal NIH cohort [n = 158], the Lübeck cohort [n = 155] and the WGET cohort [n = 180])^{12,78,99} confirm common themes with regard to morbidity and prognosis. Median follow-up times in the NIH and German cohorts were 8 and 7 years, respectively. The majority of patients in both series received daily CYC and glucocorticoids as treatment. As noted, 54% to 75% of patients achieved complete remission, but 50% to 60% of these ultimately experienced relapse (at periods ranging from 3 months to 16 years). Recent clinical trials have shown that 80% to 96% of GPA/MPA patients may experience remission with current therapies. Studies have not been homogeneous in terms of clinical definitions (e.g., of “minor disease flare”), the percentage

of patients with GPA and MPA enrolled, and the long-term use of low doses of glucocorticoids as part of the maintenance regimen; overall, however, the flare rate has been around 10% to 20% at 12 to 18 months and 30% to 70% at 24 to 36 months.^{45,71-73,78,80} Most of the exacerbations occurred after the discontinuation of maintenance therapy, which argues for the necessity of extended immunomodulation. Of note, patients with MPA seem to experience a lower rate of relapse than those with GPA.¹⁰⁰

Mortality at 1 year in GPA/MPA exceeds 15%. Infection (due to pharmacologic immunosuppression) and active vasculitis are the most important causes of early death. Eighty-six percent of the NIH patients experienced permanent disease-related morbidity, including chronic renal insufficiency (42%), hearing loss (35%), nasal deformity (28%), tracheal stenosis (13%), and visual loss (8%).¹² ESRD is seen in about 20% of these patients within 10 years.¹⁰⁰

Immunosuppressive treatments also contribute to morbidity and mortality. In the NIH series, serious infections occurred in 46% of the patients.¹² Despite the use of shorter CYC courses and new remission induction strategies with RTX, infectious complications continue to influence the prognosis of GPA/MPA patients. Other treatment-related adverse events includes CYC-induced cystitis,^{12,80,99} increased risk of malignancy (particularly bladder cancer, myelodysplastic syndrome, leukemia, and lymphoma),^{12,78} infertility,¹² and a host of adverse effects related to the use of glucocorticoids (e.g., cataracts, bone fractures, diabetes).¹² The incidence of bladder injury (cystitis) and cancer has become much lower since numerous centers have adopted induction remission strategies using shorter courses of CYC (3 to 6 months) for patients with severe disease, followed by attempts to maintain remission with AZA or MTX.

In EGPA, the presence of one risk factor (FFS = 1) and two or more risk factors (FFS ≥ 2) is associated with a 5-year mortality of 25% and 45%, respectively, and such cases warrant more aggressive therapy, whereas a FFS of 0 is associated with a mortality of 3% to 12% after the same period of time. With adequate treatment, survival in EGPA is 95% at 1 year and 60% to 97% at 5 years.¹⁰⁰ However, the use of CYC in EGPA patients is also associated with significant complications.⁸⁶

Regardless of the initial disease severity and the therapy received, nearly 80% of EGPA patients continue to have asthma that is difficult to treat. This population therefore requires continuous therapy with low to moderate doses of systemic glucocorticoids, which make a substantial contribution to the development of treatment-induced morbidity (e.g., bone fractures).^{31,86}

Patients taking immunosuppressants should receive prophylaxis against *Pneumocystis jiroveci* pneumonia; in addition, all patients who require long-term glucocorticoid therapy are at risk of osteoporosis, and treatment with calcium, vitamin D, and bisphosphonates should be prescribed according to national guidelines (e.g., those of the National Osteoporosis Foundation).

158 Takayasu arteritis

■ CAROL A. LANGFORD

- Takayasu arteritis is an inflammatory disease of unknown etiology characterized by granulomatous vasculitis affecting the aorta, its main branches, and the pulmonary arteries. It occurs most often in women of childbearing age.
- Physical examination will show absent pulses, bruits, and asymmetric blood pressure.
- Hypertension is an important contributor to morbidity and mortality.
- Common symptoms include claudication, headaches, dizziness, syncope, visual changes, dyspnea, palpitations, and vessel tenderness (carotidynia).
- Systemic symptoms may be absent but include fever, night sweats, fatigue, arthralgia, and myalgia.

HISTORY

The first descriptions of Takayasu arteritis may date from the 1700s and 1800s when several patients were reported with pulselessness and aortic disease. In 1905, Mikito Takayasu presented the case of a young woman with a wreathlike arteriovenous anastomosis around the optic disc. Caccamise and Whitman in 1952 referred to this entity as “pulseless or Takayasu disease,” and in 1962, Judge and colleagues introduced the term *Takayasu arteritis*. Although Takayasu arteritis has become the most widely used name for this disease in the United States, it is known in other countries as aortic arch syndrome, pulseless disease, middle aortic syndrome, occlusive thromboaropathy, and nonspecific aortoarteritis.

EPIDEMIOLOGY

Takayasu arteritis has often been characterized as an illness affecting young women of Eastern ethnic background. However, descriptions from diverse regions have supported the fact that it occurs throughout the world but may have a varying spectrum in different populations (Tables 158.1 and 158.2).¹⁻⁶ Although Japanese series have demonstrated a female preponderance of 9:1, nearly equal representation in men and women has been reported in Israel and India. Similarly, although Takayasu arteritis is most commonly diagnosed between the ages of 15 and 25 in Japan, it has been diagnosed in patients from Italy and Sweden at a mean age of 41 years. In Olmsted County, Minnesota, the incidence is estimated to be 2.6 cases per million.

CLINICAL FEATURES

At the time of diagnosis, 10% to 20% of patients with Takayasu arteritis are clinically asymptomatic, with the disease being detected incidentally as a result of abnormal vascular findings on examination.⁵ The remaining 80% to 90% of patients seek medical attention because of symptoms that are systemic or vascular. Systemic symptoms include fatigue, malaise, weight loss, night sweats, fever, arthralgia, or myalgia, but they may be absent in

up to 60% to 80% of patients.^{5,7,8} Vascular symptoms occur as a direct result of either active vasculitis or vascular damage from previous disease. Active inflammation may result in tenderness over the vessel, and carotidynia occurs in 2% to 32% of patients. Vessel inflammation typically results in either stenosis (Figs. 158.1 and 158.2) or aneurysm formation (Fig. 158.3). The frequencies of common symptoms, which vary between different series, are listed in Table 158.1.¹⁻⁶ Decreased circulation in the extremities is often manifested as intermittent claudication. Stenosis or occlusion of the two carotid and two vertebral arteries or the vessels proximal to their origin may be asymptomatic or be manifested as transient ischemic attacks, stroke, dizziness, syncope, headache, or visual changes. Although mesenteric involvement is common, gastrointestinal symptoms such as nausea, diarrhea, vomiting, and abdominal pain occur infrequently.

Retinal disease occurs in 14% of patients and results from compromise of the internal carotid circulation with central retinal hypoperfusion. Aortic valvular regurgitation secondary to dilation of the aortic root occurs in 5% to 55% of patients (see Fig. 155.3). Coronary vessel stenosis may develop in up to 25% of patients,⁴ with other manifestations including mitral valve regurgitation, cardiomyopathy, and myocarditis. In arteriographic studies, pulmonary artery disease may occur in 50% to 86% of patients (Fig. 158.4).^{2,3} Although it is usually mild and asymptomatic, patients may have features of pulmonary hypertension. Findings on ventilation-perfusion scans are often abnormal in this setting and may be mistaken for thromboembolic disease. Cutaneous manifestations occur in 3% to 28% of patients, with the most common lesions being erythema nodosum, pyoderma gangrenosum, erythema induratum, and ulcerative lesions. Renovascular hypertension can result in nonspecific glomerular disease secondary to arterial narrowing.

INVESTIGATIONS

Diagnosis and monitoring of disease activity

Takayasu arteritis is diagnosed by the presence of characteristic arterial lesions in the aorta and its branches, for which other causes of large-vessel abnormalities have been excluded. The American College of Rheumatology proposed classification criteria in 1990 for the purpose of providing a standard way to describe patients with Takayasu arteritis in studies.

Laboratory and radiographic investigations are initially used diagnostically and thereafter for the purpose of assessing disease activity. An inability to accurately assess disease activity in Takayasu arteritis has been a critical limitation in managing individual patients and evaluating therapeutic regimens. Currently, disease activity is typically assessed by evaluating the collective information gained from imaging, from clinical assessment of the symptoms and signs, and from laboratory studies. Despite this approach, active arteritis has been found in up to 44% of surgical bypass specimens taken from patients judged to be quiescent by current methods.⁵

Laboratory investigations

No laboratory study is diagnostic of Takayasu arteritis or correlates with active arteritis. The disease is not associated with antineutrophil cytoplasmic antibodies. Complete blood cell counts may reveal normochromic, normocytic anemia, leukocytosis, and thrombocytosis. Some series have found the erythrocyte sedimentation rate to be a useful marker for assessing active inflammatory disease,⁹ whereas others have not found it to be uniformly reliable.^{5,8} C-reactive protein can also be a marker of active inflammation in some patients, although no data are available regarding its overall utility in Takayasu arteritis.

TABLE 158.1
Common symptoms and signs (%) in Takayasu arteritis

Symptom/sign	Study					
	Japan ¹ (N = 52)	India ² (N = 106)	China ³ (N = 530)	Korea ⁴ (N = 129)	USA ⁵ (N = 60)	Mexico ⁶ (N = 107)

Fig. 158.1 Magnetic resonance arteriogram demonstrating diffuse moderate stenosis of the proximal left common carotid and proximal occlusion of the left subclavian artery coming off the aortic arch along with the development of an extensive collateral network.

Fig. 158.2 Irregularity and stenosis of the infrarenal abdominal aorta and right renal artery seen on a magnetic resonance arteriogram.

Fig. 158.3 (a and b) Aneurysm of the aortic root seen on magnetic resonance imaging (T1-weighted images). The ascending aorta measures 5.0 cm and can be compared with the normal diameter of the descending aorta.

Fig. 158.4 Pulmonary arteriogram in a patient with Takayasu arteritis. Abrupt termination of a proximal branch to the lingula is seen, as well as a vessel with irregularity and narrowing.

Radiographic studies

Diagnostic imaging is fundamental to the diagnosis of Takayasu arteritis and plays an essential role in monitoring the disease. Arteriography with catheter-directed intravascular injection of contrast dye, magnetic resonance imaging (MRI), or computed tomographic angiography (CTA) provides information on vascular luminal dimensions. Complete imaging of the aorta and its major branches should be performed in all patients at the time of diagnosis and during serial evaluation because such studies can detect clinically occult vascular disease and provide information important to diagnosis and future disease management. The noninvasive ability to look at a vessel with MRI or CTA provides a useful means of serial monitoring. In the absence of contraindications, such imaging is typically performed at 6- to 12-month intervals in those with Takayasu arteritis to monitor for the development of new vascular lesions.

Vessel stenosis is present in 85% or more of patients at the time of diagnosis and is the most common arteriographic finding (see Figs. 158.1 and 158.2). Aneurysms may be saccular or fusiform and typically affect the aorta rather than its branches (see Fig. 158.3). Various patterns of vessel involvement have been observed in different populations (see Table 158.2). Comparative studies of vessel disease across different regions have been aided by the use of arteriographic classification systems that focus on the distribution of vessel involvement (Fig. 158.5).¹⁰ After diagnosis, the development of new lesions in new vascular territories is considered by most investigators to be indicative of active disease. However, progression of previous vascular lesions may also result from noninflammatory fibrosis.

Catheter-directed dye arteriography has remained the “gold standard” for detecting and measuring the luminal dimensions of involved vessels in Takayasu arteritis. It also allows assessment of central blood pressure, which may be important in patients in whom vascular disease in the extremities does not allow accurate peripheral measurement. Limitations of dye arteriography are the risk for thromboembolism and significant exposure to contrast agent and radiation.

Magnetic resonance angiography (MRA) and CTA are safe and noninvasive techniques for assessing vessel patency in Takayasu arteritis.¹¹ The use

Fig. 158.5 (Redrawn from Hata A, Noda M, Moriwaki R, et al. Angiographic findings of Takayasu arteritis: new classification. *Int J Cardiol* 1996;54[suppl]:S155-63.)

of CTA requires exposure to radiation, and both CTA and MRA are contraindicated in the setting of renal insufficiency. In contrast to conventional arteriography, MRI also provides information on arterial wall thickness and edema with fast spin-echo sequences, although its correlation with active disease is unclear.¹¹

Ultrasonography has been reported to provide useful information, but this technique is operator dependent and additional study is required to determine its applicability.¹² The results with ¹⁸F-fluorodeoxyglucose-labeled positron emission tomography (FDG-PET) have been mixed, with some studies concluding that FDG-PET is useful for the detection of active inflammation and others finding no association between vascular intensity and clinical disease activity.^{13,14}

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of Takayasu arteritis includes atherosclerotic, inflammatory, infectious, and hereditary diseases that affect the large vessels. IgG4-related disease has emerged as a potential cause of aortitis and peri-aortitis and is histologically differentiated from Takayasu arteritis by a dense lymphoplasmacytic infiltrate rich in IgG4-positive plasma cells, a storiform pattern of fibrosis, and obliterative phlebitis.¹⁵

PATHOLOGY

Tissue biopsy plays little or no role in the diagnosis of Takayasu arteritis because histologic examination of the great vessels is usually possible only at the time of vascular procedures or after death. Takayasu arteritis is a panarteritis that typically occurs as focal “skip lesions.” During active disease, the inflammatory infiltrate is predominantly lymphocytic with granuloma formation and giant cells involving the media and adventitia. Later, degeneration of the internal elastic lamina of the media, adventitial fibrosis, and neovascularization are seen.

The pathophysiology and etiology of Takayasu arteritis remain poorly understood. The presence of granulomatous inflammation, blood vessel inflammatory infiltrates consisting of T cells and monocyte/macrophages, and high tumor necrosis factor (TNF)-producing T cells suggests that type 1 helper T-cell (Th1) mechanisms play a role in pathogenesis of the disease. Analysis of cytokine gene transcription in peripheral blood mononuclear cells has demonstrated increased constitutive mRNA expression of TNF and interleukin-4 (IL-4) and a decrease in the induced expression of IL-10 mRNA.¹⁶ In other studies, evidence of cell-mediated cytotoxicity has been provided by the demonstration of increased numbers of $\gamma\delta$ T lymphocytes with a restricted T-cell receptor, as well as $\gamma\delta$ T lymphocytes, natural killer cells, and cytotoxic T cells in aortic tissue.¹⁷ Extension of this work has found that $\gamma\delta$ T cells in patients with Takayasu arteritis are reactive to 60-kDa heat shock protein (hsp60) and cytotoxic to aortic endothelial cells, thus suggesting a role for hsp60 and $\gamma\delta$ T cells in disease pathogenesis.¹⁸ In studies from Japan, Korea, and Turkey, an association of Takayasu arteritis with HLA-B*52 has been described.¹⁹ In Indian patients, Takayasu arteritis

is associated with HLA-B*51, whereas analysis of HLA genes in North America has not revealed any association.⁵

MANAGEMENT

General principles

Treatment of active disease is based on the rationale that interruption of active inflammation before the development of significant vessel damage improves the prognosis. However, the role of immunosuppressive treatment in lessening morbidity and mortality has been difficult to assess. In a series of 30 longitudinally observed patients, 93% achieved remission but only 28% had a sustained remission, defined as the absence of clinical, laboratory, and radiographic evidence of new vascular lesions for more than 6 months while taking less than 10 mg of prednisone daily; relapses occurred in 96% of those who had achieved remission.⁷ To date, therapeutic data on Takayasu arteritis have come from open-label trials, observational studies, and case series. Therapeutic decisions are often guided by the location and severity of lesions, collateral circulation, and medication toxicity. Effective care of patients with Takayasu arteritis includes not only treatment of active disease but also nonmedical management of fixed vascular lesions or aneurysms, as well as control of comorbid features.

Conventional immunosuppressive agents

Glucocorticoids are the foundation of treatment of Takayasu arteritis. Combination therapy is considered primarily in patients who have severe disease or persistent disease activity despite glucocorticoids treatment or when remission cannot be maintained with acceptable doses of glucocorticoids. Because combination therapy increases the risk for infection, care should be taken to monitor for cytopenia and provide prophylactic treatment of *Pneumocystis jiroveci*.

Glucocorticoids

Glucocorticoids are the therapeutic mainstay for Takayasu arteritis. Resolution of systemic symptoms occurs in 25% to 100% of glucocorticoid-treated patients,^{5,6,20} and some reports have demonstrated improvement in arteriographic blood flow and return of previously absent pulses. No comparative trials have been conducted to determine the optimal dose and length of glucocorticoids treatment. In retrospective series, initial prednisone doses ranging from 20 to 100 mg/day have been used.^{6,20} In a retrospective analysis of 150 patients who had received 30 mg/day prednisolone, 51% had improved quality of life, 37% experienced no change, and 12% worsened, although the definitions of these outcome measures were not stated.²⁰ In the largest prospective standardized experience with glucocorticoids for Takayasu arteritis, in which patients initially received prednisone at a dosage of 1 mg/kg/day (60 mg daily) for the first 1 to 3 months, which was then tapered, 52% achieved remission.⁹ Although current data support the use of an initial prednisone dosage of 1 mg/kg/day, a lower starting dosage may be considered in selected individuals at high risk for glucocorticoids toxicity, provided that immediate tissue ischemia is not a threat.

Methotrexate

A prospective standardized trial evaluated the use of methotrexate (MTX) in a glucocorticoids-resistant population.²¹ In this study of 16 patients, MTX at 15 to 25 mg/wk combined with prednisone led to remission in 81%. However, remission was followed by relapse in 54%, and 19% of patients had progressive disease. Toxicities of MTX include elevated hepatic transaminase levels, stomatitis, pneumonitis, teratogenicity, and bone marrow suppression. Although this study has limitations, these data support that MTX may be an effective means of inducing remission and minimizing glucocorticoids toxicity in patients with Takayasu arteritis.

Cyclophosphamide

Cyclophosphamide (CYC) was the first cytotoxic agent studied for Takayasu arteritis; however, data regarding its use are limited.²² CYC has the potential for serious short- and long-term toxicity, including bone marrow suppression, infection, infertility, bladder injury, transitional cell carcinoma of the bladder, and myeloproliferative disease. Given the predilection for relapse and the predominantly young female population affected, CYC is rarely used for Takayasu arteritis.

Azathioprine

Valsakumar and colleagues²³ used azathioprine (AZA) combined with prednisolone to treat 15 patients with active Takayasu arteritis for 1 year.

All patients showed improvement in systemic symptoms and laboratory measures of disease activity within 3 months, and arteriograms 1 year later revealed no changes. AZA can be associated with cytopenia, infection, allergic reactions, and leukemia. Use of AZA concomitantly with glucocorticoids can be considered in patients who cannot receive MTX or who have experienced relapse after previous MTX treatment.

Other conventional immunosuppressive agents

Mycophenolate mofetil,^{24,25} leflunomide,²⁶ and minocycline²⁷ have been used in a limited number of patients, but further study will be required for their efficacy to be determined.

Biologic therapies

The use of TNF inhibitors in patients with Takayasu arteritis has been explored in a number of case series because of evidence suggesting a role of Th1 mechanisms in the development of large-vessel granulomatous vasculitis.²⁸⁻³¹ Molloy and colleagues²⁹ used TNF-modulatory agents to treat 25 patients with refractory Takayasu arteritis. Remission was achieved and prednisone was discontinued in 15 patients (60%) and tapered to a dosage lower than 10 mg daily in another 7 patients (28%); major relapses occurred in 4 patients and 4 experienced adverse events. Schmidt and associates³⁰ retrospectively studied 20 patients with refractory Takayasu arteritis treated with TNF inhibitors. Disease remission occurred in 18 patients (90%) and sustained remission in 10 (50%). Ten patients of 12 patients receiving at or above prednisone 10mg daily (83%) were able to taper the prednisone dosage to below 10 mg daily, with 7 being able to stop glucocorticoids treatment. However, 6 of 18 patients experienced relapse, 20% discontinued treatment because of adverse events, and six infections occurred in 5 patients. Although the results from these studies are encouraging, it remains difficult to determine the efficacy and relative safety of anti-TNF therapy for Takayasu arteritis in the absence of a randomized controlled trial.

Other biologic agents have prompted interest for investigation in treating Takayasu arteritis, including several case reports of use of the anti-IL-6 receptor antibody tocilizumab^{32,33} and an ongoing randomized trial of the T-cell co-stimulation modulator abatacept. However, the evidence on either of these agents is insufficient to currently support their use in clinical practice.

Antiplatelet therapy

In a retrospective study of 48 patients with Takayasu arteritis, De Souza and coworkers³⁴ found that the use of antiplatelet therapy was associated with a lower frequency of ischemic events and had a protective effect with a low frequency of bleeding complications. Even though this study is small, it suggests that in patients without contraindications, aspirin 100 to 200 mg daily may reduce the risk for acute ischemic events in patients with Takayasu arteritis.

Nonmedical interventions

Nonmedical interventions are important for the revascularization of stenosed or occluded vessels that produce significant ischemia or for the treatment of aneurysms. Up to 70% of patients with Takayasu arteritis may require nonmedical interventions, with the most frequent indications including cerebral hypoperfusion, renovascular hypertension, limb claudication, repair of aneurysms, and valvular insufficiency.

The safety and potential benefits of vascular reconstructive surgery in patients with Takayasu arteritis have been favorable, but occlusion and complication rates vary greatly between series.³⁵⁻³⁸ Although surgery is more invasive than other forms of vascular intervention, current studies suggest that it results in a higher rate of patency over time.^{35,37} Ideally, vascular reconstruction should be deferred until the acute inflammation is controlled medically because aneurysm formation, graft dehiscence, or graft occlusion may be more likely in the setting of active arteritis.^{36,38} The role of perioperative glucocorticoids in clinically quiescent patients remains unclear. The site of revascularization is also important with regard to the long-term outcome, and care should be taken to avoid placing surgical connections to vessels that are frequently known to become involved during the course of disease. Bypass grafts for involved cervicobrachial vessels should ideally originate from the ascending aorta because this segment rarely becomes stenotic.

Percutaneous transluminal angioplasty (PTCA) can be effective in acutely improving blood flow. In settings in which renal artery PTCA is undertaken, care must be taken to minimize sudden drops in blood pressure

in patients who have severe stenoses across critical vascular beds. The ability of PTCA to acutely reduce stenosis has varied widely, but it transiently improved blood pressure in the majority of patients. However, the longevity of results is variable, with some studies suggesting a substantial restenosis rate.³⁵

Percutaneously placed stents have also been used for Takayasu arteritis. Similar to the experience with PTCA, the short-term results have been encouraging, but some series have found a high rate of restenosis or occlusion over extended follow-up.^{35,37} A recent report has described the use of stent grafts for Takayasu arteritis.³⁹ Although this intervention appears to be associated with better results than can be achieved with bare metal stents, longer-term patency data will be needed to understand the durability and role of this endovascular therapy in these patients.

Management of comorbid features

Hypertension has been reported to occur in 32% to 93% of patients¹⁻⁶ and it contributes to renal, cardiac, and cerebral injury. Because the subclavian arteries are a frequent site of vessel stenosis, blood pressure measurements in one or both arms may not be representative of aortic root pressure, and therefore four-extremity blood pressure measurements should be taken at each clinic visit. When treating hypertension, care should be taken to avoid precipitous drops in blood pressure, particularly in patients with compromised cerebral blood flow. Because evidence supports the finding that patients with Takayasu arteritis have a high rate of plaque formation,

proactive assessment and effective control of traditional atherosclerotic risk factors are also essential.

OUTCOME

The long-term outcome of patients with Takayasu arteritis has varied between studies. Although North American reports found overall survival rates to be 94% or greater,^{5,7} the 5-year mortality rate has been as high as 35%.^{3,9} Disease-related mortality can occur as a result of congestive heart failure, cerebrovascular events, myocardial infarction, aneurysm rupture, or renal failure.^{1,3,4,8,9} Takayasu arteritis is associated with substantial morbidity. In one series, 74% of patients exhibited compromised function in activities of daily living and 47% were permanently disabled.⁵

Pregnancy

For women not being treated with cytotoxic therapy, pregnancy is not contraindicated, but careful perinatal care is important to optimize outcomes in both the mother and child. Although the amount of data is still limited, most series have reported favorable maternal and fetal outcomes.^{5,40} Hypertension is the most common cause of complications and must be monitored closely. Induction of labor or cesarean section is not mandatory for women with Takayasu arteritis, although advanced planning for the method of delivery is important.⁴⁰

159 Behçet syndrome

■ SEBAHATTIN YURDAKUL ■ VEDAT HAMURYUDAN ■ HASAN YAZICI

- Behçet syndrome is a systemic vasculitis of unknown etiology that is characterized by recurrent mucocutaneous manifestations and chronic relapsing uveitis with the potential threat of blindness. It may involve veins and arteries of all size.
- A marked geographic distribution exists along the "Silk Route," with the greatest prevalence rates found in Turkey, Iran, and Japan.
- Behçet syndrome occurs most commonly in the second or the third decades and has an undulating course that generally abates in intensity with the passage of time.
- Men and those in whom the disease develops at a young age have a more severe disease course.
- Frequent recurrent oral and genital ulcerations and a variety of other skin manifestations occur, including the "pathergy" phenomenon.
- Other complications include musculoskeletal, large-vessel, neurologic, and gastrointestinal involvement.

HISTORY AND EPIDEMIOLOGY

In 1937 Hulusi Behçet from Istanbul described three patients with oral and genital ulcerations, hypopyon-related uveitis, and erythema nodosum.¹ Additional clinical manifestations, including musculoskeletal, neurologic, vascular, and gastrointestinal involvement, were recognized later and added to the disease spectrum.^{2,3} The underlying pathology includes an inflammatory process of arteries and veins.

The usual onset of Behçet syndrome occurs in the third decade. Onset is rare in people 50 years or older and before puberty. Both genders are affected equally, but men and the young have a more severe disease course.⁴

The global distribution suggests a geographic pattern coincident with the ancient Silk Route, with the highest incidence found in the Middle and Far East. The prevalence of Behçet syndrome has been reported to be between 20 and 421 per 100,000 adults in five field surveys in Turkey. These figures compare with 17 in Iraq, 80 in Iran, and 120 per 100,000 in an Arab community in Israel. Estimated prevalence ranges are 0.64 in the United Kingdom, 6.4 in Spain, and 5.2 in the United States per 100,000 population. Similar low frequencies are seen in indigenous Germans (1.47/100,000), whereas Turks living in Berlin, Germany, still have a distinctly high rate of 77 per 100,000.⁵

Even with the low figures in Europe, in the suburbs of Paris the frequency of Behçet syndrome was higher (7.1/100,000) than the frequencies of Wegener granulomatosis, Churg-Strauss syndrome, and microscopic polyarteritis nodosa taken individually and close to the frequency of all three diseases combined (9/100,000).⁵

Disease prevalence shows ethnic variation even in the same city: ethnic Armenians living in Istanbul have a lower frequency of Behçet syndrome (110/100,000) than the general population does (420/100,000).⁶ Immigrant Turks in Berlin have a higher frequency than ethnic Germans do, indicative of a genetic load, but have a lower frequency than Turks living in Turkey do, indicative of an environmental influence. Similarly, the higher frequency of Behçet syndrome in Arabs in Israel might signify both genetic and environmental factors, with the latter perhaps related to lower social strata.

ETIOLOGY

Genetic and environmental factors play a role, although the exact contribution of each is unknown.

Genetic factors

The syndrome does not show mendelian inheritance. The increased prevalence of the disease along the Silk Route, an increased sibling recurrence rate (λ_s , 11 to 53) in Turkey, and the involvement of another family member (1/10) in endemic areas suggest a genetic element. A meta-analysis showed that the most frequent association is with HLA-B51/B5, which has been validated in various ethnic groups.⁷ A whole-genome analysis has recently identified 16 additional loci and 2 other non-HLA loci such as interleukin-10 (IL-10) and IL23R-IL12RB2, thus pointing to a true complex genetic disorder.^{8,9}

Several other genes such as the major histocompatibility complex class I chain-related genes (MIC), tumor necrosis factor (TNF), and the heat shock proteins¹⁰ and their various polymorphisms have been identified, but it is not clear whether they are in linkage disequilibrium with HLA-B51 or independently affect susceptibility.

Environmental factors

The hypersensitivity to *Streptococcus sanguis* antigens, their sequence homology with various heat shock proteins, and their potential cross-reactivity suggest a pathogenetic role. Herpes simplex virus type 1, *Staphylococcus aureus*, and *Prevotella* species, which are found in nonsterile pustular skin lesions, have also been suggested as potential candidates.¹¹ However, no infectious agent has yet been causally linked to Behçet syndrome.

CLINICAL FEATURES

The manifestations of Behçet syndrome tend to recur either alone or in combination (Table 159.1). Mucocutaneous lesions constitute the hallmark of Behçet syndrome, but uveitis and neurologic and large-vessel manifestations are the most serious.

Mucocutaneous lesions

Oral aphthous ulcerations (Fig. 159.1a) are usually the first and most frequent manifestation. The oral ulcers of Behçet syndrome are generally indistinguishable from ordinary canker sores; however, they are generally multiple and recur more frequently. Minor aphthous ulcers (<10 mm in diameter) are the most common type ($\approx 90\%$) and heal without scarring; major or herpetiform ulcers are less frequent. Major ulcers can leave scars.

Genital ulcerations (see Fig. 159.1b) typically develop on the scrotum (90%) and less frequently on the penis in men and on the labia majora (70%) followed by the labia minora in women. They heal with scarring in about two thirds of patients when they are large (≥ 1 cm in diameter).¹² Urethritis and dysuria are not usually present.

Mainly three types of skin lesions are found:

1. Erythema nodosum-like lesions (see Fig. 159.1c) are confined to the lower extremities and commonly heal with residual pigmentation, as distinct from idiopathic erythema nodosum or lesions secondary to other causes. Histologic examination of these lesions shows more

Fig. 159.1 Mucocutaneous findings in Behçet syndrome. (a) Oral aphthae. (b) Genital ulceration. (c) Erythema nodosum–like nodular lesions. (d) Multiple positive pathergy tests.

TABLE 159.1
Frequency of the clinical manifestations of Behçet syndrome and classification criteria of the International Study Group

Manifestation	Frequency (%)
Oral ulcers	97-99
Genital ulcers	≈85
Papulopustular lesions	≈85
Erythema nodosum	≈50
Pathergy reaction	≈60 (Mediterranean countries and Japan)
Uveitis	≈50
Arthritis	≈50
Subcutaneous thrombophlebitis	25
Deep vein thrombosis	≈10
Arterial occlusion/aneurysm	≈4
Central nervous system involvement	10
Epididymitis	≈10
Gastrointestinal lesions	1-30 (more prevalent in Japan)

*In the absence of other clinical explanations, patients must have the following:
Recurrent oral ulceration (aphthous or herpetiform) observed by the physician or patient at least three times in a 12-month period plus two of the following:*

- Recurrent genital ulceration*
- Eye lesions: anterior uveitis, posterior uveitis, cells in the vitreous by slit-lamp examination, or retinal vasculitis observed by an ophthalmologist*
- Skin lesions: erythema nodosum, pseudofolliculitis, papulopustular lesions, or acneiform nodules in postadolescent patients not treated with corticosteroids*
- Positive pathergy test read by a physician at 24 to 48 hours*

vasculitic elements than occurs with idiopathic erythema nodosum or other causes.¹³

2. Superficial thrombophlebitis (Fig. 159.2) may also appear as a nodular skin lesion mimicking erythema nodosum. Superficial thrombophlebitis may be associated with deep vein thrombosis.

Fig. 159.2 Superficial thrombophlebitis.

3. The acne-like lesions are usually indistinguishable from ordinary acne.¹⁴ They occur not only at the usual sites of acne but also at uncommon sites such as the legs and arms.

In addition, papular lesions, consistent with cutaneous vasculitis and Sweet syndrome (neutrophilic dermatosis), can also be associated with Behçet syndrome.

The pathergy reaction

The pathergy reaction (see Fig. 159.1d) represents hyperreactivity of the skin to trauma. Typically, it is characterized by erythematous papule or pustule formation at a skin site 24 to 48 hours after insertion of the needle. This phenomenon is quite specific for Behçet syndrome. However, wound healing after biopsy-induced trauma is normal. The frequency of pathergy positivity is 60% to 70% in Turkey and Japan, but it is rarely observed in patients from northern Europe or the United States.¹⁵

Fig. 159.3 Hypopyon uveitis.

Eye involvement

Eye involvement occurs in 50% of patients. It is more frequent and more severe in men and the young. This chronic, relapsing uveitis is mostly bilateral, involves both the anterior and posterior uveal tracts, and leads to significant morbidity. Anterior uveal tract inflammation frequently leads to photophobia and red eye, whereas posterior tract inflammation is characterized by visual loss. Hypopyon-related uveitis (**Fig. 159.3**) is seen in 20% and indicates a poor prognosis because it is almost always associated with severe retinal disease. Isolated anterior uveitis is infrequent, and conjunctivitis is rare.

Posterior uveal inflammation with involvement of the retina can be severe. Retinal lesions consist of exudates, hemorrhages, papilledema, and macular disease. Postinflammatory structural changes, including synechiae and retinal scars, are important determinants of the prognosis of the eye disease.

Musculoskeletal involvement

Behçet himself described “rheumatoid pains” in 1938, 1 year after the original description. Seen in up to 50% of patients, the typical features of joint involvement include a nondeforming, nonerosive peripheral monoarthritis or oligoarthritis that lasts not more than a few weeks. The knees are involved most frequently, followed by the ankles, wrists, and elbows. Synovial fluid is commonly inflammatory, but a good mucin clot is usual. Synovial histology shows nondiagnostic, nonspecific synovitis.^{16,17}

Occasionally, chronic arthritis and osteonecrosis can be seen. Back pain is uncommon, and properly conducted studies of sacroiliac joint involvement have not demonstrated an increased prevalence in Behçet syndrome.¹⁷

Patients with Behçet syndrome and arthritis also have more acne lesions. Furthermore, patients with arthritis and acne have significantly more enthesopathy. Behçet syndrome with arthritis and acne forms a distinct cluster that was significantly more common in familial cases, thus interestingly suggesting genetic predisposition for a particular disease cluster.¹⁸ However, sacroiliitis and HLA-B27 were not increased in this cluster.

Fibromyalgia can develop, especially in female patients. Local or systemic myositis occurs rarely in both the proximal and distal ends of extremities in patients with Behçet syndrome.

Neurologic disease

Neurologic involvement is observed in 5% to 10% of patients. Parenchymal involvement (80%), commonly involving the brain stem, is manifested by pyramidal, cerebellar, and sensory signs and symptoms along with sphincter disturbances and behavioral changes. Isolated cerebellar involvement is unusual. Nonparenchymal involvement (20%) is characterized by dural sinus thrombi, with intracranial hypertension being manifested as headaches and papilledema. Simultaneous parenchymal and nonparenchymal involvement is unusual. Parenchymal involvement has a more severe course. Cerebrospinal fluid examination is nonspecific, with a high protein or cell count implying a more guarded prognosis. Peripheral nerve disease, seen frequently in other vasculitides, is uncommon.¹⁹

Fig. 159.4 Pulmonary artery aneurysms on a chest radiograph.

Venous and arterial lesions

Vascular lesions develop in a fourth to a third of patients, mostly in males. Thrombophlebitis of superficial (see **Fig. 159.2**) or deep veins is most frequent in the legs. Thrombosis of major vessels, such as vena cava obstruction and occlusion of the suprahepatic veins (Budd-Chiari syndrome), occurs less frequently. Despite the frequent occurrence of venous involvement, thromboembolism is rare because of the tight adherence of thrombi to the diseased endothelium.

The entire arterial tree can be affected, with aneurysms or occlusions (or both) in the abdominal aorta and the carotid, femoral, and popliteal arteries.²⁰ Behçet syndrome is the only vasculitis that can cause pulmonary artery aneurysms, which are the leading cause of death.²¹ Recurrent hemoptysis is the main manifestation. The aneurysms are seen as noncavitating opacities on chest radiographs (**Fig. 159.4**). The diagnosis can be confirmed by computed tomography or magnetic resonance imaging.

Cardiac involvement

Valvular lesions, myocarditis, pericarditis, coronary vasculitis, coronary and ventricular aneurysms, and intracardiac thrombus formation have been reported infrequently (6%) and portend a poor prognosis.²² A study that compared the clinical, electrocardiographic, and echocardiographic findings of patients with Behçet syndrome and healthy control subjects did not find a difference between the two groups.²³ Unlike many other chronic vasculitides, increased atherosclerosis is not a major problem with Behçet syndrome.²⁴

Lung disease

Apart from pulmonary artery aneurysms, isolated thrombosis of peripheral segments of the pulmonary arteries with or without aneurysms can be seen. Both types of involvement can occur together and have similar clinical findings and prognosis. Nodules, cavities, and consolidations are frequently confused with secondary infections in an immunocompromised patient. Mediastinal lymphadenopathy and pleural and pericardial effusions may be observed. Patients may have pulmonary artery hypertension.²⁵

Gastrointestinal involvement

Mucosal ulcerations, primarily in the ileum²⁶ and colon, cause colicky abdominal pain, diarrhea, and bleeding. Ileocecal lesions are prone to perforation. Gastrointestinal involvement is seen in about a third of patients from Japan but is less common in those from the Mediterranean basin.

Other clinical findings

Glomerulonephritis has been reported sporadically. Amyloidosis of the AA type can accompany and cause nephrotic syndrome. Epididymitis (10%) is

a well-recognized feature of Behçet syndrome. Bladder involvement can result in voiding dysfunction.² Patients exhibiting features consistent with coexistent Behçet syndrome and relapsing polychondritis (mouth and genital ulcers with inflamed cartilage—MAGIC syndrome) have been described. These patients have various combinations of oral and genital ulcerations, thromboembolic disease, ocular inflammation, and gastrointestinal ulcerations along with nasal and auricular chondritis.

Finally, auditory and vestibular lesions, presumably caused by vasculitis, are more frequently recognized in patients with Behçet syndrome.

PROGNOSIS

A recent survey of the 20-year outcome of a cohort of 427 patients with Behçet syndrome revealed that men and those young in age at onset of the disease have a more stormy course and increased mortality. Mortality was highest in patients 14 to 24 years of age at their first visit,²⁷ similar to a recent report from France.²⁸ It decreased, however, as time passed. Exacerbations of the undulating course become less frequent as the patients aged. On the other hand, about 60% of patients would not have fulfilled any set of criteria for diagnosis at the end of 20 years, which means that the majority of patients go into a remission once they pass the initial, active disease years.²⁷

Ruptured pulmonary and peripheral aneurysms and neurologic and gastrointestinal involvement are the major causes of mortality.²⁷ Budd-Chiari syndrome and amyloidosis also carry a guarded prognosis.²⁸

INVESTIGATIONS

Laboratory findings are nonspecific. A moderate anemia of chronic disease and leukocytosis are seen in about 15% of patients. The erythrocyte sedimentation rate and C-reactive protein value may be mildly elevated. However, these parameters are not good indicators of disease activity. Autoantibodies such as rheumatoid factor, antinuclear antibody, anticardiolipin, and antineutrophilic antibodies are absent.

DIFFERENTIAL DIAGNOSIS

A set of classification criteria have been developed (see Table 159.1).²⁹ Using recurrent aphthous ulceration as an obligatory feature, these criteria require the presence of two other sets of organ involvement for diagnosis.

Patients with recurrent aphthae in addition to only one organ manifestation are considered to have “incomplete” disease and present a diagnostic challenge. Diseases in the differential diagnosis and their characteristic features are presented in Table 159.2. The seronegative arthritides and inflammatory bowel disease constitute the main difficulties in the differential diagnosis, especially in the West. Without the help of extraintestinal manifestations it might be impossible to differentiate Behçet syndrome from Crohn disease.

PATHOGENESIS

Behçet syndrome is an inflammatory vasculitis of unknown etiology that can involve all types and sizes of arteries and veins. The absence of typical necrotizing vasculitis and giant cell formation in histology specimens coupled with the propensity for venular involvement and the presence of pulmonary and arterial aneurysms is unique (Fig. 159.5).³⁰

A type 1 helper T (Th1) cell–mediated immune response and hypersensitivity to nonspecific trauma as exemplified by the pathergy test are characteristic. A proinflammatory innate immune system–derived activation that is sustained by adaptive immune responses is thought to be important in pathogenesis.³¹ The observation of a potential genetic impairment in the production of IL-10,^{8,9} an inflammation-suppressing molecule, and an augmented IL-21–driven Th17 pathway³² are recent considerations in pathogenesis.

A coagulation abnormality, though extensively sought, has not been found to explain the high frequency of venous thrombosis. A decrease in fibrinolysis is probably the most consistent finding.

Neutrophil hyperreactivity has also been an important issue. However, it is not clear whether the activity is inherent in the neutrophil or is due to the priming cytokines that are abundant in the circulation.

Behçet syndrome does not easily fit into any proposed classes because the disease does not have the classic group characteristics, such as urethritis,

TABLE 159.2
Differential diagnosis of Behçet syndrome

Disease	Features not seen in Behçet syndrome
Reactive arthritis	Urethritis, penile lesions on the glans penis, conjunctivitis
Seronegative arthropathies	Mainly psoriatic skin lesions, aortic insufficiency, frequent axial involvement
Inflammatory arthropathies	Serologic abnormalities
Inflammatory bowel disease	Inflammatory lesions throughout the bowel
Multiple sclerosis	Intranuclear ophthalmoplegia, optic neuritis
Sarcoidosis	Bilateral hilar adenopathy, parenchymal pulmonary disease
Other systemic vasculitides	Microaneurysms, mononeuritis multiplex, antineutrophil cytoplasmic antibodies
Vogt-Koyanagi-Harada syndrome	Peliosis, alopecia, vitiligo
Stevens-Johnson syndrome	Blisters, corneal involvement
Venereal diseases	Glans lesions, specific serologic studies
Coxsackievirus and echovirus infections	Subacute course
Relapsing polychondritis	Nasal and auricular chondritis

Fig. 159.5 This high-power photomicrograph shows fresh thrombus formation and prominent lymphoplasmacytic infiltration in the entire wall of the elastic artery. Perivascular inflammatory infiltration of adventitial tissue is also present together with vasa vasorum arteritis (hematoxylin-eosin, x100). (Courtesy Dr. Buge Oz.)

balanitis, sacroiliitis, and HLA-27 association for the seronegative spondyloarthritis; female preponderance, Raynaud phenomenon, Sjögren syndrome, and specific antibodies for autoimmune diseases; and the predominance of fever and pediatric involvement, gene mutations such as the TNF receptor or pyrin, and the CARD/NOD gene associations of Crohn disease for autoinflammatory disorders.³³ Clinical observations have suggested that there are clusters of disease expression in Behçet syndrome. One such cluster consists of superficial and deep vein thrombosis, dural sinus thrombi, and pulmonary arteries, and another is the cluster of acne, arthritis, and enthesitis.³³ These clusters suggest that more than one disease mechanism may be operative in the pathogenesis of Behçet syndrome.

MANAGEMENT

The aim of the treatment is to prevent organ damage. The type and severity of symptoms along with prognostic factors determine the therapeutic strategy. Prophylactic immunosuppressive therapy with azathioprine might be considered for young men during the initial years of the disease because they carry the highest risk for the development of severe complications in the long term.^{34,35}

TABLE 159.3
EULAR recommendations for the management of Behçet syndrome

Manifestation	Recommended therapy
Eye involvement	Azathioprine combined with corticosteroids is recommended as the first-line agent for all patients with posterior uveitis.
Refractory eye involvement	In the case of visual loss (>2-line drop in visual acuity on a 10-scale chart) or retinal involvement (retinal vasculitis or macular involvement), the addition of cyclosporine or infliximab to azathioprine and corticosteroids is recommended. Interferon alfa with or without corticosteroids may be another alternative.
Vascular involvement	Immunosuppressives such as corticosteroids, azathioprine, cyclosporine, and cyclophosphamide are recommended for venous involvement. Cyclophosphamide along with corticosteroids is recommended for arterial involvement. However, firm evidence for these recommendations is lacking.
Thrombophilia	No data, even uncontrolled, support the use of anticoagulant, antiplatelet, or fibrinolytic agents for the management of deep vein thrombosis or arterial lesions.
Gastrointestinal involvement	Sulfasalazine, corticosteroids, azathioprine, TNF- α antagonists, and thalidomide should be considered before surgery, except in emergencies.
Arthritis	Colchicine will be effective for most patients. Azathioprine, interferon alfa, and TNF- α antagonists may be considered for refractory cases.
CNS involvement	For parenchymal involvement, corticosteroids, azathioprine, interferon alfa, cyclophosphamide, methotrexate, and TNF- α antagonists are recommended. Dural sinus thrombosis can be managed with corticosteroids.
CNS involvement and cyclosporine	Cyclosporine should not be used in patients with CNS involvement unless definitely necessary for ocular inflammation.
Mucocutaneous involvement	Mild oral or genital ulcers may be managed with topical measures (corticosteroid- or lidocaine-containing creams, sucralfate suspension). Erythema nodosum can be managed with colchicine. Azathioprine, interferon alfa, and TNF- α antagonists are recommended for refractory cases.

CNS, central nervous system; EULAR, European League Against Rheumatism; TNF, tumor necrosis factor.

Adapted from Hotemi G, Silmon A, Bong D, et al. EULAR recommendations for the management of Behçet disease. *Ann Rheum Dis* 2008;67:1656-62.

Controlled trials are limited to mucocutaneous manifestations and eye involvement, but no formal evidence is available for treatment of the vascular, neurologic, and gastrointestinal manifestations. An European League Against Rheumatism task force proposed nine recommendations for the management of Behçet syndrome (Table 159.3).³⁶

Mucocutaneous lesions are treated according to their severity. Topical cream (e.g., triamcinolone acetonide cream) may provide symptomatic relief. Colchicine (1 to 2 mg/day) is recommended for mild to moderately severe manifestations and especially for erythema nodosum and genital ulcers.³⁷ Thalidomide (100 mg/day) is highly effective in treating severe oral and genital ulcers, but severe adverse effects such as teratogenicity and polyneuropathy prevent prolonged use of this drug.³⁸ Azathioprine is effective in suppressing frequent recurrences of oral and genital ulcers. Uncontrolled studies of infliximab and adalimumab and one short-term randomized controlled trial of etanercept suggest that TNF- α inhibitors are effective in controlling refractory mucocutaneous manifestations.^{39,40}

Arthritis can be often managed with colchicine.³⁷ Short courses of corticosteroids and nonsteroidal agents may provide symptomatic relief. Sulfasalazine, azathioprine, TNF- α antagonists, and interferon alfa may be considered for long-lasting or frequently recurring arthritis attacks.

Azathioprine combined with corticosteroids is the first-line treatment of uveitis, which most frequently involves the entire globe.^{36,41,42} The presence of retinal involvement or a significant drop in visual acuity necessitates the addition of either cyclosporine or a TNF- α antagonist to the combination of azathioprine and corticosteroids. Interferon alfa, alone or with corticosteroids, is another alternative. The daily dose of azathioprine is 2.5 mg/kg, and a minimum of 3 months is required for commencement of its effect. Cyclosporine is rapidly effective in reducing the frequency and severity of ocular attacks, as well as in improving visual acuity, but relapses of uveitis have been reported after cessation of cyclosporine. The daily dose of

cyclosporine should not be higher and should preferentially be lower than 4 to 5 mg/kg, with close monitoring for adverse effects, especially nephrotoxicity. Use of cyclosporine is not recommended in patients with central nervous system involvement unless absolutely indicated.³⁶ Infliximab, even with a single dose, may rapidly suppress attacks of uveitis.⁴⁰ However, its effect is not long-lasting and thus continuous treatment is required. Adalimumab is another alternative, and switching from one TNF- α antagonist to another when required appears to be effective.⁴³ The effect of interferon alfa starts rapidly, and it may induce long-lasting drug-free remission.⁴⁴ The optimal dose of interferon alfa has not been determined yet.⁴⁵

The use of anticoagulants for the management of venous thrombosis is still a matter of debate. New information suggests that treatment with azathioprine and corticosteroids significantly reduces recurrences of venous thrombosis.⁴⁶ Cyclophosphamide combined with high-dose corticosteroids is used for arterial aneurysms. Pulmonary aneurysms are generally bilateral and multiple and tend to recur; surgery should thus be the last choice. Endovascular embolization can replace surgery in an emergency, but the very frequent coexistence of venous thrombosis may render this intervention technically difficult. Surgery for peripheral aneurysms should always be supported with immunosuppressive agents to prevent relapses.⁴⁷

The course of gastrointestinal involvement is not infrequently complicated by relapses requiring resection of large bowel segments. Sulfasalazine, 5-aminosalicylic acid, azathioprine, corticosteroids, thalidomide, and TNF- α antagonists have been used anecdotally to prevent recurrences.³⁶

Parenchymal central nervous system involvement is initially treated with pulsed corticosteroids. TNF- α antagonists, azathioprine, cyclophosphamide, methotrexate, and interferon alfa are used to prevent relapses. Dural sinus involvement usually responds to treatment with corticosteroids. Blockade of IL-1 and IL-6 appears to be on the horizon as a promising target.

160 Kawasaki disease

■ JANE C. BURNS ■ ADRIANA H. TREMOULET

- Kawasaki disease (KD) is the most common cause of acquired heart disease in children in the United States, Western Europe, and Japan.
- KD is not a rare disease, with more than 5000 and 12,000 new cases diagnosed each year in the United States and Japan, respectively.

HISTORY

Historical investigation suggests that the systemic vasculitis that we now call *Kawasaki disease* (KD) was new in the East and old in the West.¹⁻³ Records from Western Europe and the United States from the late 19th and early 20th centuries document a pathologically indistinguishable vasculitis in infants that was called *infantile periarteritis nodosa* and was diagnosed only at autopsy.⁴ In 1967 Dr. Tomisaku Kawasaki reported on a series of 50 patients in Japan with a syndrome that he named *mucocutaneous lymph node syndrome*.⁵ Not until a nationwide epidemiologic survey was performed in 1970 in Japan was it appreciated that this clinical syndrome was associated with coronary artery aneurysms that could lead to myocardial infarction and death. An English-language version of Kawasaki's original patient series report was published in 1974, and the term *Kawasaki disease* was proposed in 1977 by Landing and Larson.^{4,6} Today, KD is recognized as the most common cause of acquired pediatric heart disease in nations across the globe and has been identified in all ethnic groups and races.^{7,8}

EPIDEMIOLOGY

In Japan, the country of highest incidence, there were 240 cases per 100,000 children (younger than 5 years of age) in 2010.⁹ In the United States, there is no effective active surveillance program, and incidence estimates are extrapolated from insurance databases. The incidence in the United States in 2000 based on hospital discharge diagnoses was 17.1 per 100,000 children younger than 5 years of age.¹⁰ Important regional differences in incidence within the United States suggest a genetic influence on disease susceptibility, and rates per 100,000 children younger than 5 years are 210 for Japanese American children in Honolulu, 43 for children of Filipino descent in San Diego, and 15 for a largely African American population in Detroit.¹¹⁻¹³ Familial occurrence is increasingly being reported.^{14,15} Based on a 2009-2012 nationwide survey in Japan, there was a 3.6% recurrence risk, 1.6% occurrence of sibling cases, and 0.7% occurrence in children with a history of KD in one or both parents.⁹

KD cases cluster in both time and space, which lends support to the theory that there is an infectious trigger for the disease.¹⁶ In both Japan and the United States there is a biphasic occurrence of the disease with peaks in the winter/spring and again in midsummer.^{17,18} A recent analysis has linked fluctuations in KD case numbers with tropospheric wind patterns that originate in Central Asia.¹⁹

CLINICAL FEATURES

No laboratory test exists to confirm the diagnosis of KD, and the clinician must use clinical criteria in conjunction with supportive laboratory data to establish the diagnosis. Updated guidelines for the diagnosis of complete and incomplete KD are available from the American Heart Association²⁰ (Box 160.1).

The exanthem can take many different forms but is never frankly bullous or vesicular (Fig. 160.1). Micropustules (less than 1 mm) may occur over extensor surfaces, genitals, and the upper buttocks.²¹ The rash is accentuated in the groin in 50% of patients.²² Unlike in bacterial toxin-mediated illnesses such as scarlet fever, there is rarely generalized desquamation of the rash. In general, the rash is not pruritic except in children with a history of eczema. Both psoriasis and eczema are associated with KD, and the first flare of these chronic skin conditions may occur during the convalescent phase of KD.^{23,24}

Injection of the bulbar conjunctiva with associated perilimbal sparing is noted in the majority of patients (Fig. 160.2). Unlike in viral conjunctivitis, there is no conjunctival inflammation and no exudate or tearing, and both eyes become injected at the same time.^{25,26} Anterior uveitis is seen in over 80% of patients examined by slit lamp during the first week after fever onset.²⁷

Changes in the oropharynx include fissured red lips, strawberry tongue, and oropharyngeal erythema without discrete lesions or ulcers. The fissuring of the lips usually occurs in the center portion of the vermillion border. Tonsillar exudate is not a feature of KD.²⁸

Changes in the extremities include edema of the dorsa of hands and feet and palm and sole erythema, which is distinct from the rash (Fig. 160.3). Periungual desquamation in the convalescent phase may occur on the fingers or toes or both and is noted in approximately two thirds of patients (Fig. 160.4).²⁹ Transverse grooves across the nail bed (Beau lines) appear 4 to 6 weeks after fever onset. Arthritis was prospectively documented in 30% to 40% of patients in the preimmunoglobulin era, and more recently arthritis or arthralgia was noted in 7.5% to 15% of patients in retrospective studies.³⁰⁻³² Arthritis of the small joints of the fingers is common and is often associated with a bluish discoloration over the proximal interphalangeal joints. Axial arthropathy with frank arthritis or arthralgia may be associated with joint effusions with a neutrophil predominance and cell counts of 20,000 to 200,000 cells/mm³.³¹

A painful, unilateral cervical lymph node mass is noted in approximately one third of patients.²⁸ A misdiagnosis of bacterial cervical lymphadenitis frequently delays the diagnosis of KD and appropriate treatment.³³ Imaging studies show a "cluster of grapes" appearance of the node mass, in contrast with the more common single, hypodense node associated with localized bacterial infection.³⁴ KD patients with cervical node enlargement tend to be older and have higher levels of inflammatory markers than patients with bacterial infection.³⁵

The most serious clinical findings are associated with the cardiovascular system. Although myocarditis is universally present based on biopsy studies, a gallop rhythm is noted only in approximately one third of patients and frank congestive heart failure is rare during the acute phase. A new clinical presentation with high-output shock associated with hypotension has been described.^{36,37}

Other clinical manifestations of KD may include the following: gastrointestinal manifestations including hydrops of the gallbladder and pancreatitis, urethritis, facial nerve palsy (rare), and sensorineural hearing loss (fewer than 1% of cases). Minor associated symptoms are frequent and, in a recent series, included gastrointestinal symptoms (vomiting, diarrhea, or abdominal pain; 61% of cases) and respiratory tract symptoms (cough or rhinorrhea; 35% of cases).³²

LABORATORY ASSESSMENTS

Laboratory testing is used to document high levels of systemic inflammation and to rule out other rash/fever syndromes as appropriate based on the history and findings of the physical examination (Fig. 160.5).³⁸ A minimum laboratory evaluation should include the following: complete

BOX 160.1 CLINICAL CRITERIA FOR CLASSIC KAWASAKI DISEASE

Fever persisting at least 4 days in the presence of four of five principal clinical criteria:

1. Polymorphous rash
2. Bilateral conjunctival injection without exudate
3. Changes in the oropharynx, including red fissured lips, strawberry tongue, and red pharynx without exudate
4. Changes in the extremities, including edema of the dorsa of the hands and feet, palm and sole erythema, and periungual desquamation during the convalescent stage (usually 2 to 3 weeks after fever onset)
5. Enlarged cervical lymph node of at least 1.5 cm (usually unilateral)

Fig. 160.1 Polymorphous exanthem over the limbs and trunk of an infant with acute Kawasaki disease.

Fig. 160.2 Conjunctival injection, red fissured lips, and left cervical lymphadenopathy in a patient with acute Kawasaki disease.

Fig. 160.3 Edematous, erythematous feet in a patient with acute Kawasaki disease. (Courtesy the Kawasaki Disease Foundation.)

Fig. 160.4 Periungual desquamation of the fingers and toes 2 to 3 weeks after fever onset in a patient with Kawasaki disease.

blood cell count with manual differential count, erythrocyte sedimentation rate (ESR), C-reactive protein level, alanine aminotransferase level, γ -glutamyltranspeptidase level, albumin level, and urinalysis.^{28,39}

Echocardiographic assessment and electrocardiography should be performed according to the guidelines of the American Heart Association, and the internal diameter of the right coronary artery and left anterior descending coronary artery and aortic root should be expressed as standard deviations from the mean normalized for body surface area (z score).^{20,40-43} Tissue Doppler imaging is useful to detect diastolic dysfunction.⁴⁴

PATHOLOGIC FEATURES

KD is a systemic vasculitis that primarily affects medium-sized, extraparenchymal musculoelastic arteries and shows a predilection for the coronary

LABORATORY ABNORMALITIES DURING THE FIRST 10 DAYS AFTER FEVER ONSET AND BEFORE TREATMENT IN PATIENTS WITH ACUTE KAWASAKI DISEASE

Fig. 160.5 Abnormal laboratory results seen in patients with acute Kawasaki disease. ALT, alanine aminotransferase; CRP, C-reactive protein; CSF, cerebrospinal fluid; ESR, erythrocyte sedimentation rate. GGT, γ -glutamyltranspeptidase; WBC, white blood cells.

Fig. 160.6 Selective coronary angiogram showing a giant aneurysm of the left coronary artery.

arteries.⁴⁵ Myofibroblast infiltration with secretion of proinflammatory cytokines, matrix metalloproteinases, and elastases destroys the structural integrity of the vessel wall and can result in aneurysm formation (Fig. 160.6).⁴⁶ Three linked vasculopathic processes characterize the acute and chronic pathologic changes in the vessel wall and include an acute, self-limited necrotizing arteritis, a subacute or chronic vasculitis, and luminal myofibroblastic proliferation.

The necrotizing arteritis, which occurs during the first 2 weeks after onset of fever, is characterized by infiltration with neutrophils from the lumen of the vessel. Myocarditis is universal at this stage and can progress to fibrosis and scarring in the later stages.⁴⁷

During the subacute/chronic vasculitis, which may begin within the first 2 weeks after fever onset, there is an infiltration of small lymphocytes, plasma cells, and eosinophils from the adventitial vasa vasorum, which progresses toward the lumen. Aneurysms of the coronary arteries with or without thrombosis can occur. Immunohistochemical testing shows a predominance of CD8⁺ T cells and macrophages infiltrating the vessel wall with secretion of matrix metalloproteinases during this stage.^{48,49} Infiltration of immunoglobulin A-secreting plasma cells is also noted.⁵⁰

A different vasculopathic process involves a progressive, asynchronous intraluminal stenosis mediated by vascular smooth muscle cell-derived myofibroblasts. This process is associated with intimal thickening, remodeling of aneurysms, thrombotic occlusion, and stenosis in the medium-sized arteries.

ETIOLOGY AND PATHOGENESIS

Most investigators agree that a microbial agent triggers the immune response that characterizes acute KD. Many infectious agents have been proposed and discarded as candidates for the causative agent of KD.⁵¹ Intracytoplasmic inclusions that stain with a synthetic antibody constructed from sequences derived from KD plasma cells have been proposed as evidence of a viral cause.⁵² It is possible that multiple agents trigger the syndrome in genetically susceptible hosts.

An understanding of the complex genetics of KD has been pursued through candidate gene studies, family linkage studies, and genomewide association studies.⁵³⁻⁵⁶ A functional polymorphism in the inositol-1,4,5-trisphosphate 3-kinase gene that affects interleukin-2 signaling through the NFAT/calcineurin pathway confers increased susceptibility and also increased risk of aneurysm formation.⁵⁷ Genetic variation in the transforming growth factor- β signaling pathway confers increased risk of aneurysm formation.⁵⁸ Further studies are necessary to capture the sum of the genetic diversity that influences KD susceptibility and outcome.

TREATMENT AND MANAGEMENT

Based on large-scale clinical trials in the 1980s, the current recommended treatment for KD patients is a single intravenously administered dose of immunoglobulin (IVIG, 2 g/kg) in conjunction with high-dose aspirin (80 to 100 mg/kg/day).⁵⁹ After cessation of fever, most centers reduce the aspirin dosage to a low antiplatelet dosage of 3 to 5 mg/kg/day. The aspirin is continued until the ESR and platelet count have returned to the normal range. This approach, if implemented within the first 10 days after fever onset, reduces the incidence of coronary artery aneurysms from 25% to 5%.

IVIG resistance, defined as persistent or recrudescence fever (temperature of 38.0°C or higher) at least 36 hours after the end of the initial IVIG infusion, can occur in patients at highest risk of coronary artery damage.⁶⁰ Originally described as affecting only 10% to 15% of KD patients, IVIG resistance has now increased to 20% to 30% of patients in some regions of the United States and Japan.^{61,62} Strategies to treat IVIG resistance have included a second infusion of IVIG, a single infusion of infliximab, corticosteroids, cyclosporine, and plasmapheresis.⁶³⁻⁶⁶ Prospective identification of patients at risk of IVIG resistance would allow intensification of initial treatment.⁶⁷ Risk scores have been devised in Japan, but their application to populations outside of Japan has not been successful, possibly due to the mixed ethnic composition of the population.^{60,68} A large, prospective, randomized multicenter trial in the United States examined the addition of pulsed methylprednisolone to IVIG in the initial treatment of KD patients, but no benefit was demonstrated.⁶⁹ In contrast, a prospective, randomized, open-label study of the addition of a 15-day course of steroids to primary therapy with IVIG in Japan in risk score-selected KD patients demonstrated improved coronary artery outcomes.⁶⁴ The use of corticosteroids at any point during the treatment of acute KD remains controversial.⁷⁰ In a retrospective study, patients treated with infliximab for IVIG-resistant KD had faster resolution of fever and fewer days of hospitalization but no difference in coronary artery outcome compared with patients treated with a second dose of IVIG.⁷¹ A randomized, double-blind, placebo-controlled trial of infliximab plus IVIG for initial treatment of KD patients has completed enrollment, and data are currently being analyzed.

Arthritis persisting after treatment with IVIG usually responds well to naproxen or a single dose of infliximab. It is rare for patients to require treatment for arthritis beyond the subacute phase.

Management of cardiovascular complications should be undertaken by pediatric and adult cardiologists familiar with evolving treatment guidelines. Studies using historical controls suggest a benefit of warfarin therapy (to an international normalized ratio of 2.0 to 2.5) for patients with giant aneurysms (8 mm or more in internal diameter).^{72,73} Antiplatelet therapy with aspirin and/or clopidogrel is recommended for all patients with persistent dilatation or aneurysms, although prospective trials have not been performed.²⁰

Some centers perform echocardiography at 5-year intervals in all children and young adults after KD owing to the emerging recognition of arrhythmia, sudden death, myocardial fibrosis, and congestive heart failure in individuals with no documented coronary artery lesions during the acute phase of the illness.⁷⁴ Because arterial calcification is a common feature of KD vascular lesions, obtaining a computed tomographic coronary artery calcium score several years after acute KD may help identify individuals with significant vasculopathy.⁷⁵ Evidence-based guidelines for the long-term care and management of KD patients into adulthood are evolving.

Henoch-Schönlein purpura/
immunoglobulin-A vasculitis

■ SEZA OZEN ■ YELDA BILGINER

- Henoch-Schönlein purpura is currently termed immunoglobulin A (IgA) vasculitis now that the role of IgA in its pathogenesis is more apparent.
- A set of classification criteria have been newly developed for children and may help pediatricians in making the diagnosis as well.
- Evidence-based data are desperately needed for the treatment of kidney involvement, although this is one of the most common childhood vasculitides.

DEFINITION

Henoch-Schönlein purpura (HSP), a primary vasculitis of childhood that predominantly affects small vessels, is characterized by a characteristic purpura, abdominal pain, arthritis, and renal involvement. It is the most common childhood vasculitis in most parts of the world. HSP has been defined by the Chapel Hill Consensus Criteria 2012 (CHCC2) as a vasculitis with IgA1-dominant immune deposits that affect small vessels (predominantly capillaries, venules, or arterioles), often involves the skin and gut, and frequently causes arthritis.¹ Thus HSP will be termed HSP/IgA vasculitis in this chapter. The CHCC2 also stated that glomerulonephritis indistinguishable from IgA nephropathy may occur and suggested the new name to be IgA vasculitis.¹

Although the first description is attributed to Heberden in 1896,² Schönlein proposed the diagnostic triad of purpuric rash, arthritis, and abnormalities in the urinary sediment and called the disease “*peliosis rheumatica*” in 1837.³ Subsequently, his student Henoch described the gastrointestinal and renal manifestations of the disease.⁴

EPIDEMIOLOGY

HSP/IgA vasculitis occurs most often in children between the ages of 3 and 10 years, and the peak age at onset occurs between 4 and 6 years.^{5,6} It has a slight male preponderance (1.5:1), unlike other rheumatologic diseases.⁷ Though rare, it is also seen in infants, adolescents, and adults. In North America the incidence of HSP is 13.5 to 18 per 100,000, but a large population-based survey from a multiethnic region of the United Kingdom reported an annual incidence of 20.4 per 100,000.^{5,6} HSP has also been reported to have an incidence of 12.9 per 100,000 children in Taiwan and 10.2 per 100,000 children in the Czech Republic.^{8,9} Most cases occur in the winter and are often preceded by an upper respiratory tract infection.¹⁰

The incidence in adults, however, is only 1.3 per 100,000 with a mean age at diagnosis of about 50 years.¹¹ The disease is known to have a more severe course in adults.

CLASSIFICATION

The American College of Rheumatology (ACR) defined criteria for the classification of HSP in 1990. The ACR criteria require the presence of at least two of the following: (1) 20 years or younger at onset, (2) palpable purpura, (3) bowel angina, and (4) histologic changes showing granulocytes in the small walls of arterioles and venules.¹² In 2006 pediatricians suggested a new set of criteria, which were later revised based on a large multinational registry.¹³ The new criteria, published as the Ankara 2008 criteria, were endorsed by the European League Against Rheumatism, the Pediatric Rheumatology European Society, and the Paediatric Rheumatology International

Trials Organisation (Table 161.1). According to these criteria, palpable purpura is a mandatory feature, age as a criteria has been removed, arthritis/arthralgia was added, and the finding of granulocytes in biopsy specimens was replaced by IgA deposition. This new classification provides 100% sensitivity and 87% specificity for the classification of HSP.^{13,14}

ETIOLOGY AND PATHOGENESIS

HSP/IgA vasculitis is a multifactorial immune complex disease. The exact etiology of HSP remains unknown; however, a number of concepts are important in the pathogenesis of the disease.

Environmental factors

Infectious agents, drugs, and vaccinations have been implicated as possible triggers of HSP. A seasonal distribution of the disease, a frequent history of a preceding upper respiratory tract infection, and a higher incidence in childhood point to an infectious etiology. Although group A streptococci have been studied the most, other viral and bacterial pathogens have been postulated, such as parvovirus B19, *Bartonella henselae*, *Helicobacter pylori*, varicella, rubella, rubeola, hepatitis A and B, and *Mycoplasma pneumoniae*.¹⁵⁻²²

In adults, drugs such as angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor antagonists (losartan), antibiotics (clarithromycin), nonsteroidal antiinflammatory drugs (NSAIDs), vaccinations, insect bites, and food allergies have been reported as precipitating factors for HSP.²³⁻²⁶

Immunologic factors

IgA has a key role in the pathogenesis of HSP. The clinical manifestations of HSP are due to deposition of IgA1 in vessel walls and the renal mesangium. It has been hypothesized that introduction of microbes through respiratory tract or gastrointestinal mucosa leads to activation of the mucosal immune system, which increases an abnormally glycosylated polymeric IgA production.^{27,28} The subsequent formation of IgA immune complexes in target organs leads to a series of inflammatory events that result in vasculitis in the respective tissues. IgA may also bind to endothelial cells and either induce endothelial cell lysis by activation of complement or directly activate endothelial cells to produce interleukin-8 (IL-8).²⁷

In HSP nephritis, levels of aberrantly glycosylated IgA1 (galactose deficient O-linked glycans) are increased, similar to patients with IgA nephropathy.^{29,30} This shed light on the pathogenesis of HSP nephritis, and it has been suggested that polymeric galactose-deficient IgA1 is recognized by naturally occurring antiglycan IgA1 or IgG, and circulating immune complexes are formed.^{28,31} Once deposited in the mesangium, the IgA immune complexes initiate the ensuing glomerular inflammation.²⁸

Although IgA has a key role in its pathogenesis, HSP is a systemic inflammatory disease, and research is ongoing to determine the role of specific inflammatory markers in the pathogenesis of the disease. Cellular immunity is also increasingly being implicated. Some proinflammatory cytokines such as tumor necrosis factor- α , IL-6, IL-8, and recently, IL-17 have been found to be increased in children with acute HSP.³²⁻³⁶

Genetic background

Increased occurrence in family members supports a genetic predisposition for this vasculitis.³⁷⁻³⁹ Several reports suggest that HLA class II polymorphisms can be a risk factor for HSP.^{39,40} An association between HLA-B35

TABLE 161.1
EULAR/PRINTO/PRES (Ankara, 2008) criteria for Henoch-Schönlein purpura*

Criterion	Definition
Purpura (mandatory)	Palpable purpura or petechiae with lower limb predominance and at least 1 of 4 of the following:
Abdominal pain	Diffuse, acute, colicky pain. Intussusception and gastrointestinal bleeding may be seen
Histopathology	Leukocytoclastic vasculitis with predominantly IgA deposition or proliferative glomerulonephritis with predominantly IgA deposition
Arthritis or arthralgias	Acute joint swelling or pain with limitation of motion or acute joint pain without joint swelling or limitation on motion
Renal involvement	Proteinuria >0.3 g for >24 hr or spot albumin-to-creatinine ratio >30 mmol/mg on a spot morning sample; hematuria or red blood cell casts >5 red blood cells/high-power field or ≥2+ on dipstick

*If the purpura has an atypical distribution, demonstration of IgA deposits on a biopsy specimen is required.

and risk for nephritis has also been suggested.⁴¹ The association with ACE gene polymorphisms remains controversial, although it may have a role in selected patients.⁴² Mutations in the gene associated with familial Mediterranean fever have been associated with the disease in certain ethnic groups.⁴³

CLINICAL FINDINGS

HSP/IgA vasculitis is an acute, systemic disease, and the classic signs and symptoms of the disease include purpura, arthralgia/arthritis, abdominal pain, and glomerulonephritis. Symptoms may be experienced within several days or weeks.⁵ An upper respiratory infection usually precedes the disease.^{15,16,17,22} Low-grade fever and fatigue are often present.^{44,45} Clinical characteristics of patients with HSP/IgA vasculitis are presented in Box 161.1.

Cutaneous involvement

The predominant cutaneous finding in patients with HSP is palpable purpura, which is also mandatory for diagnosis¹⁴ (Fig. 161.1). The purpuric rash is most prominent on dependent areas such as the extensor surface of the lower extremities, the belt line, and the buttocks, but it may also be seen on the arms, face, and ears.^{15,46} In addition, skin lesions may be found on the scrotum, penile shaft, and glans penis.⁴⁷ Rarely, petechiae, ecchymoses, and hemorrhagic bullae can be seen. The cutaneous lesions progress in color from red to purple to brown before fading. In children the eruption is characterized by its polymorphism, whereas in adults it is frequently monomorphic.^{15,23} Hemorrhagic necrotic lesions are more often seen in adults.⁴⁸ Especially in young children, subcutaneous edema may develop in the scalp, face, dorsa of the hands and feet, scrotum, or elsewhere.⁴⁹

Joint involvement

Arthralgia and arthritis occur in 60% to 80% of patients and may precede the rash in up to a quarter of patients with HSP.^{15,45} The arthritis is often monoarthritis and is characterized by periarticular swelling and pain and limitation of motion. The joint disease is nonmigratory and transient and resolves without residual abnormalities.⁴⁵

Gastrointestinal involvement

Gastrointestinal involvement, including colicky abdominal pain, vomiting, and gastrointestinal bleeding, occurs in 50% to 75% of children, usually within a week after onset of the rash. Gastrointestinal signs and symptoms may rarely precede the purpura.^{15,50} Abdominal pain is the most common

gastrointestinal symptom and is often periumbilical and epigastric and worsens after meals.⁵¹ Intestinal bleeding manifested as gross or occult blood occurs in approximately a third of children. Intussusception develops in 1% to 5% of children and is mostly ileoileal in location.^{45,46} Perforations, usually ileal, may occur spontaneously or be associated with intussusception.⁵² Less common involvement includes acute pancreatitis, hepatobiliary involvement, and enteropathy.^{45,53-55}

Renal involvement

Renal involvement has been reported to occur in 20% to 60% of children.^{15,46,56} Clinical findings range from the more common transient, isolated microscopic hematuria and mild proteinuria to the less common nephrotic syndrome, nephritic syndrome, rapidly progressive glomerulonephritis, and renal failure. Nephritis rarely develops before appearance of the characteristic rash.^{15,50}

Renal disease develops in most children within the first 6 weeks and in the remaining within 6 months.⁵⁷ Age older than 7 years at onset, severe abdominal symptoms, persistent purpuric lesions, and decreased factor XIII activity are associated with increased risk for nephritis.^{45,58-60} Renal manifestations are less likely to develop in children younger than 2 years.⁶¹ In longitudinal studies of unselected patients, the risk for chronic renal impairment is 2% to 15% and that for end-stage renal disease is lower than 1%.⁵⁶

Renal involvement is detected in 45% to 85% of cases of adult-onset HSP, with a 30% risk for progression to renal insufficiency.⁶² It has been reported that patients older than 20 years with gastrointestinal involvement at onset and persistent eruption are more likely to progress to renal disease.^{63,64}

Genitourinary involvement

Orchitis occurs in 10% to 20% of boys with HSP and may mimic testicular torsion.^{15,50} There are also single reports of ureteral stenosis in patients with HSP.⁶⁵

Neurologic involvement

Neurologic involvement has been reported in 1% to 8% of children and affects mostly those with either severe kidney disease or uncommon features.^{66,67} Central nervous system dysfunction results from vascular obstruction, intracerebral hemorrhage, or severe hypertension.⁶⁸ Possible neurologic findings include headache, altered level of consciousness, seizures, focal neurologic deficits, visual abnormalities, verbal disability, peripheral neuropathy, and facial palsy.^{66,67}

Pulmonary involvement

Although pulmonary hemorrhage is a very rare complication of HSP, especially in children, it is associated with high morbidity and mortality. Clinical symptoms of pulmonary hemorrhage include hemoptysis, dyspnea, chest pain, and anemia.^{69,70}

Malignancy

HSP has been associated with malignancy, most commonly with solid tumors in adult patients⁷¹ but not in children.

Pregnancy

Onset of HSP has been reported both during pregnancy and in the postpartum period. Establishing a diagnosis of HSP in pregnancy can be difficult because of the importance of distinguishing other vasculitides (skin involvement), obstetric emergencies, acute abdomen, labor (abdominal pain), and preeclampsia (nephritis). Women who had HSP as a child are more likely to have proteinuria or hypertension during pregnancy.⁶⁸

DIAGNOSIS

No specific laboratory test is available for the diagnosis of HSP. Moderate leukocytosis and mild anemia as a result of gastrointestinal bleeding can be identified in some children. Acute-phase reactants may be elevated. Urinalysis might reveal hematuria, proteinuria, or both. In patients with renal disease and urinary abnormalities, the degree of proteinuria should be defined and renal function tests should be performed. Stool should be examined for frank or occult blood.⁷² An increase in IgA is seen in 50% of cases, and circulating IgA-containing immune complexes may be present in some patients, but

TABLE 161.2

Laboratory features of Henoch-Schönlein purpura/IgA vasculitis

Investigations	Possible findings
Initial investigations	
Complete blood count	May reveal leukocytosis and/or anemia
Acute-phase reactions (erythrocyte sedimentation rate/C-reactive protein)	Normal or elevated
Urinalysis	Normal, hematuria, and/or proteinuria
Stool guaiac examination	Normal, positive
Secondary investigations (indicated according to clinical features and abnormal results of the above)	
Urine protein/creatinine	Normal, increased, nephrotic range
Renal functional tests	Normal, elevated creatinine, hypoalbuminemia
Plain abdominal supine radiograph and chest radiograph	Normal, air leak
Abdominal ultrasonography	Thickened bowel wall, intussusception
Tests for differential diagnosis	
Blood culture	Specific infections
Imaging procedures and relevant biopsies	To differentiate from PAN
Antineutrophil cytoplasmic antibody (ANCA)	ANCA-associated vasculitis
Antinuclear antibodies, anti-double-stranded DNA, complement 3	SLE, hypocomplementemic urticarial vasculitis
PAN, polyarteritis nodosa; SLE, systemic lupus erythematosus.	

these findings are not specific for the diagnosis.^{45,72} Other laboratory studies are useful to exclude diseases that should be included in the differential diagnosis. Platelet number and clotting test results are normal. Serologic tests such as antinuclear antibodies and rheumatoid factor are negative, and C3 and C4 are normal and need not be studied for diagnosis.

Abdominal ultrasonography or computed tomography is the preferred diagnostic modalities for imaging intussusception in children with HSP because barium enemas may miss the ileoileal location.⁵² Ultrasonography may show asymmetric bowel wall thickening secondary to vasculitis involving the gastrointestinal system, mainly the jejunum and ileum.¹⁵ Scrotal ultrasonography could be helpful if scrotal involvement is suspected (Table 161.2).

Skin biopsy is helpful if the rash is atypical; it reveals leukocytoclastic vasculitis involving the capillaries and venules of the mid and upper dermis and, with direct immunofluorescent studies, shows perivascular deposition of IgA, C3, and fibrinogen in the affected vessel wall.^{15,73}

Indications for renal biopsy in children are (1) nephritic/nephrotic proteinuria; (2) raised creatinine, hypertension, or oliguria; (3) heavy proteinuria (urinary albumin-to-creatinine ratio persistently >100 mg/mmol) on an early morning urine sample at 4 weeks; (4) persistent proteinuria after 4 weeks; and (5) impaired renal function.^{45,74}

HSP/IgA vasculitis-associated nephritis is characterized by mesangial damage with different degrees of hypercellularity ranging from isolated mesangial proliferation to focal and segmental proliferation and severe crescentic glomerulonephritis. Mesangial diffuse IgA deposits are the hallmark of the disease. IgA1 is the dominant subclass. C3 is deposited in 75% to 85% of cases⁷⁶ (Figs. 161.2 and 161.3).

DIFFERENTIAL DIAGNOSIS

HSP/IgA vasculitis should be distinguished from acute hemorrhagic edema of infancy, immune thrombocytopenic purpura, hemolytic-uremic syndrome, systemic lupus erythematosus, disseminated intravascular coagulation, infections, hypersensitivity vasculitis, and other type of vasculitis.^{45,46} It should be borne in mind that the gastrointestinal symptoms can mimic a surgical abdomen, infectious enteritis, or inflammatory bowel disease in the absence of the characteristic rash (see Table 161.2).

Fig. 161.2 Renal biopsy specimen showing segmental mesangial proliferation and expansion of the mesangial matrix.

Fig. 161.3 Immunopathology—mesangial IgA deposition.

TREATMENT

Because HSP is a self-limited disease, the external manifestations of the disease are managed with appropriate symptomatic measures. For those with joint involvement and painful inflammatory soft tissue edema, analgesics such as acetaminophen and NSAIDs can be used (Table 161.3).⁷⁷⁻⁸⁴ To date, however, no study has examined the efficacy of NSAIDs for HSP. One should be aware of the gastrointestinal and renal side effects of these drugs, albeit rare in children.

The use of steroids is reserved for patients with gastrointestinal involvement. Prednisone is generally taken at dose of 1 mg/kg/day for 2 weeks, with weaning over the subsequent 2 weeks. However, in patients who need to be admitted to the hospital, steroids must be administered intravenously.⁸⁵ A randomized double-blind placebo-controlled study confirmed that short-term steroid therapy decreased the intensity and duration of gastrointestinal symptoms and the severity of joint symptoms.^{78,79}

Despite the lack of evidence-based data for the management of severe cutaneous lesions or extensive bullae in patients with HSP, steroid and dapsone are recommended therapies for these patients.⁸⁰ Scrotal and testicular involvement is another HSP manifestation that can benefit from a short-term course of steroids.^{5,86}

Severe or life-threatening disease is rare; however, if pulmonary or central nervous system involvement or the kidney disease is progressing

TABLE 161.3

Treatment of Henoch-Schönlein purpura/IgA vasculitis

Evidence-based recommendations	Evidence
Arthritis/arthralgia with NSAIDs	D
Severe skin bullous lesions with steroids	D
Gastrointestinal involvement with steroids	
Reduces the intensity of abdominal pain	B
Reduces the mean resolution time	A
Renal involvement	
Early prednisone treatment does not prevent renal disease	A
Moderate nephritis

Data from references 78 to 84.

rapidly, heavy immunosuppressive drugs and plasma exchange are indicated, just as for any severe systemic vasculitis.

Treatment of Henoch-Schönlein purpura-associated nephritis

Management of HSP nephritis is still controversial because we lack prospective, randomized controlled studies that have investigated the treatment of HSP in patients with renal involvement. Furthermore, it is difficult to interpret the efficacy of treatment because spontaneous recovery can occur in patients with severe initial findings. More importantly, long follow-up is required because late progression to chronic kidney disease can be seen in patients with mild symptoms.

We have a good level of evidence that the use of steroids early in the course of the disease does not prevent the development of nephritis.^{78,81-83} However, we lack such data for the treatment of kidney disease once it develops.

Moderate nephritis

This group would include patients with less than 50% crescents on renal biopsy, no renal failure, and the presence of heavy proteinuria. Zoffenalla and Fanos⁸⁴ reviewed the management of HSP nephritis and concluded that there was insufficient firm evidence to guide best practice in the management of HSP nephritis. Corticosteroids have been advocated for these patients either alone or in combination with immunosuppressive agents. Various treatment regimens have been proposed, including ACE inhibition, tonsillectomy, cyclophosphamide, and azathioprine.^{45,75,87,88} In view of the similarities with IgA nephropathy, ACE inhibitors should be prescribed for all patients with persistent proteinuria.⁸⁹

Rapidly progressive glomerulonephritis

More than 50% crescents and heavy proteinuria are poor prognostic factors for HSP/IgA vasculitis-associated nephritis, and therefore treatment is aimed at preventing long-term morbidity in high-risk patients. Although we lack well-designed controlled studies for such patients, intensive therapy should be considered, including steroids and cyclophosphamide with or without plasma exchange.^{90,91} A recent study failed to show additional benefit of cyclophosphamide in adults with severe HSP over steroids alone.⁹² However, more prospective data are needed. Other options recommended for the treatment of severe HSP nephritis are cyclosporine, azathioprine, and mycophenolate mofetil.⁹³⁻⁹⁵ Very rare case reports suggest the use of rituximab for resistant cases.⁹⁶

Renal transplantation

IgA mesangial deposition frequently recurs after renal transplantation, even though recurrence of the clinical symptoms of HSP is unusual. The disease status of the recipient and other factors may affect IgA production and its deposition in the newly grafted kidney.⁷⁶ Although risk for recurrence had been reported to be as high as 35% and risk for graft loss secondary to recurrence to be 11%,⁹⁷ Kanaan and colleagues⁹⁸ found recurrence rates to be lower than previously reported. The actuarial risk for recurrence in a first

Fig. 161.4 BP, blood pressure; UC, urinary creatinine; UP, urinary protein.

graft was 11%, and the risk for graft loss as a result of recurrence was 7.5% at 10 years.

OUTCOME AND PROGNOSIS

If severe gastrointestinal or renal complications are not present, HSP/IgA vasculitis is a self-limited disorder. The duration of the disease is less than 14 days in approximately a third of patients, 2 to 4 weeks in a third, and longer than 4 weeks in the remaining third.^{99,100} Patients should be described as having prolonged disease if the symptoms persist for longer than 12 weeks.^{15,49} A variety of infections can precipitate HSP. Recurrence develops in around a third of cases, generally within 4 months of resolution of the symptoms.¹⁰¹

The prognosis is good for most children. Gastrointestinal involvement causes early morbidity, whereas renal disease causes late morbidity. In general, patients with microscopic hematuria have an excellent prognosis.⁵⁷ Nephritis complicated by nephrotic syndrome, a histologic finding of crescents in more than 50% of glomeruli on renal biopsy, and heavy proteinuria during follow-up were associated with a poor prognosis.^{46,101,102} A multicenter study of 443 patients with HSP/IgA nephritis from Turkey reported

that although all the patients in whom end-stage renal disease developed (1.1%) had nephritic-nephrotic syndrome at initial evaluation, logistic regression analysis did not show any association of the initial symptoms and histology with outcome.¹⁰³ Thus, although heavy proteinuria and deterioration of renal function seem to affect the outcome adversely, we lack evidence-based data for clinical or biopsy findings to serve as precise predictors of the ultimate outcome in all patients. On the other hand, Narchi⁵⁷ reviewed 12 studies that included 1133 children, which provided important data on the subject. Renal impairment occurred in 1.6% of those with isolated urinary abnormalities and in 19.5% of those in whom nephritic or nephrotic syndrome had developed. Thus patients with nephrotic proteinuria need to be treated and monitored closely. Patients with microscopic hematuria should be assessed annually because of the possibility of late renal deterioration. Narchi⁵⁷ recommended that because no long-term renal impairment occurred if the findings on urinalysis were normal, there is no need for follow-up after the first 6 months in those whose urinalysis results remain normal. A practical pathway to guide patients with renal involvement is presented in Figure 161.4. It has been recommended that patients with normal findings on urinalysis undergo follow-up for at least 1 year. Patients who have had clinical nephritis should be monitored closely for at 5 five years, and those with significant proteinuria or deteriorating renal function should undergo biopsy.

Cutaneous vasculitis and panniculitis

■ JEFFREY P. CALLEN ■ LUIS REQUENA

- Cutaneous vasculitis is characterized by polymorphonuclear inflammation of small to medium-sized vessels in the skin. Although circulating immune complexes are involved in its pathogenesis, a complex interaction of cytokines and vasoactive amines with endothelial cells is necessary for disease expression.
- Panniculitis represents an inflammation within adipose tissue, most commonly the subcutaneous fat, and is classified as septal, lobular, or mixed form.
- A variety of associated systemic diseases and clinical syndromes occur in patients with vasculitis or panniculitis.
- Therapy depends on the severity of the disease and the presence of systemic involvement or associated conditions.

CLASSIFICATION

Vasculitis

Many classification systems have been proposed for all forms of vasculitis, beginning with that of Pearl Zeek in the 1950s and extending most recently to those of the American College of Rheumatology and the Chapel Hill Consensus Conference.¹ Unfortunately, most of these systems do not satisfy the needs of dermatologists because small-vessel disease may occur in many of the entities.² Therefore the presence of dermatologic features such as palpable purpura, urticarial lesions, nodules, ulcers, or livedo reticularis with histologic evidence of leukocytoclastic vasculitis (LCV) indicates the likelihood that a vasculitic process will affect the skin and possibly internal organs.

Panniculitis

Panniculitis is defined as an inflammatory reaction affecting the subcutaneous tissue, which consists primarily of fat. The panniculitides are traditionally divided into four categories based on histopathologic criteria (Box 162.1): (1) mostly septal panniculitis without vasculitis, (2) mostly septal panniculitis with vasculitis, (3) mostly lobular panniculitis without vasculitis, and (4) mostly lobular panniculitis with vasculitis.³

Erythema nodosum is primarily a septal panniculitis without vasculitis that is a reactive process secondary to a variety of underlying disorders, most commonly sarcoidosis, infections, or exposure to certain drugs. Weber-Christian disease is a lobular panniculitis, but this term is outmoded because many of the patients so described have been found to have an associated abnormality such as pancreatic disease or factitial disease.

PATHOLOGIC, CLINICAL, AND SYSTEMIC FEATURES

Cutaneous vasculitides

The lesions observed in patients with cutaneous vasculitis can vary from transient urticaria-like lesions to necrosis of wide areas of skin.² The type of lesion, in general, reflects the size of the vessel involved and thus varies somewhat with the specific vasculitic syndrome. The most common

cutaneous findings in patients with vasculitis is palpable purpura (Fig. 162.1), followed by urticaria-like lesions.

Histopathologic features

Histopathologically, in the cutaneous lesions of either palpable purpura or urticaria-like lesions there is involvement of the postcapillary venules of the superficial plexus, which demonstrate necrosis of endothelial cells, fibrin deposits with the vessel walls, extravasation of erythrocytes, and infiltration of neutrophils, including their breakdown, with leukocytoclasia manifested as the presence of nuclear dust (Fig. 162.2). In some patients, eosinophils might also be present in the infiltrate, which might indicate that the disease is drug induced.⁴

Palpable purpura

The development of palpable purpura is dynamic, often beginning as non-palpable purpura. As the process progresses, some lesions become papular, nodular, bullous, infarctive, or ulcerative.⁵ The lesions fade as the reparative processes begin. These lesions most frequently occur on dependent surfaces, such as the legs. Palpable purpura is characterized by smooth, discrete papules with relatively uniform lesional hemorrhage. When the lesions are arranged in a retiform (netlike) pattern and are superficial purpuric plaques with multifocal areas of hemorrhage and necrosis, an immunoglobulin A–associated vasculitis may be more common (Fig. e162.1).⁶ The lesions of vasculitis can, on occasion, become generalized.

Urticarial lesions

Urticarial lesions of vasculitis are the second most common cutaneous manifestation (Fig. 162.3). These lesions differ from those of common urticaria, which is associated with transient pruritic lesions that last for no longer than several hours and resolve without any residual alteration, in the following ways: the individual lesions are most often long-lived, lasting between 6 and 72 hours; the lesions may resolve with some residual pigmentation or ecchymosis (Fig. 162.4); the lesions are often characterized by pain or burning rather than pruritus; and the patients tend to have symptoms or signs of multisystem disease, such as arthralgia, fever, gastrointestinal pain, lymphadenopathy, or abnormal urine sediment. The lesions of urticarial vasculitis are usually generalized. Demonstration of the long-lived nature of these lesions can be achieved by circling several lesions and evaluating them for the onset of resolution.

Other cutaneous lesions

A wide array of other cutaneous lesions can also occur, including erythematous plaques, erythema multiforme-like lesions, annular lesions, nodules, ulcerations (Fig. e162.2), necrosis, and livedo reticularis. Table 162.1 lists the varying, yet overlapping, cutaneous manifestations that occur in the traditional vasculitic syndromes. The occurrence of palpable purpura, the hallmark of LCV, in all syndromes except large-vessel vasculitis has resulted in some of the controversy surrounding the classification.

Systemic manifestations

The systemic manifestations correlate with the syndrome and the size of the vessel involved (Box 162.2). This section focuses on small-vessel vasculitis. Henoch-Schönlein purpura is considered in Chapter 161, and polyarteritis nodosa, granulomatosis with polyangiitis (Wegener granulomatosis), and eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome) are covered in Chapters 155 and 157.

The most common systemic manifestation of vasculitis is involvement of organs with a rich vascular supply, such as the gut, the kidneys, the lungs, and the musculoskeletal system. In a study of 82 patients selected for

Fig. e162.1 Retiform purpuric plaques in a patient with immunoglobulin A-associated vasculitis.

Fig. e162.2 Leukocytoclastic vasculitis with ulceration in a patient with rheumatoid arthritis.

BOX 162.1 CLASSIFICATION OF THE PANNICULITIDES**Mostly septal panniculitis without vasculitis**

- Erythema nodosum
- Vilanova disease: subacute nodular migratory panniculitis

Mostly lobular panniculitis without vasculitis

- Idiopathic neutrophilic panniculitis
- Subcutaneous fat necrosis of the newborn
- Postcorticosteroid panniculitis
- Calcifying panniculitis
- Pancreatic panniculitis
- α_1 -Antitrypsin deficiency
- Physical or factitial panniculitis
- Histiocytic cytophagic panniculitis
- Lipodystrophy syndromes
- Connective tissue panniculitis
- Subcutaneous panniculitis–like T-cell lymphoma
- Sclerosing panniculitis: lipodermatosclerosis

Mixed panniculitis

- Lupus profundus: lupus erythematosus panniculitis
- Erythema nodosum–like lesions of Behçet syndrome

Panniculitis with vasculitis

- Small-vessel vasculitis (postcapillary venule), also known as *leukocytoclastic vasculitis*
- Medium-sized-vessel vasculitis (arterioles or small arteries): *polyarteritis nodosa*
- Erythema induratum, also known as *nodular vasculitis*

Fig. 162.1 Palpable purpura representing a small-vessel vasculitis that on histopathologic study was shown to be a leukocytoclastic vasculitis.

cutaneous LCV, only about 50% had any systemic manifestations that were clinically evident, and in general this group of patients had involvement that was not life threatening.⁷ Similarly, Blanco and colleagues⁸ found that in a majority of patients with cutaneous vasculitis the disease had a relatively benign course. However, their data for adults differed from those for children.

Vasculitic syndromes with prominent cutaneous disease**Acute hemorrhagic edema of infancy**

Acute hemorrhagic edema of infancy is a rare condition that occurs in infants younger than 2 years of age.⁹ It has an acute onset, often following an upper respiratory tract infection or drug ingestion. The rash begins as urticarial plaques but rapidly becomes intensely purpuric (Fig. e162.3), frequently with annular lesions. Fever and generalized edema are common. Acute hemorrhagic edema of infancy has been distinguished from Henoch-Schönlein purpura by clinical and immunologic differences.

Fig. 162.2 Leukocytoclastic vasculitis. (a) Inflammatory reaction surrounding the small dermal vessels. (b) Fibrinoid necrosis of the vessel wall with a neutrophilic infiltrate; leukocytoclasia is present.

Fig. 162.3 Hypocomplementemic urticarial vasculitis.

Hypocomplementemic urticarial vasculitis

McDuffie and coworkers¹⁰ first described hypocomplementemic urticarial vasculitis when they reported on four patients with recurrent attacks of erythematous urticarial and hemorrhagic skin lesions associated with synovitis and, sometimes, abdominal distress. Their patients did not have lupus erythematosus or paraproteinemia but did have hypocomplementemia; two had nephritis.

Fig. e162.3 Acute hemorrhagic edema of infancy. In this patient palpable purpura is accompanied by edema of the legs.

Fig. 162.4 Residual bruising evident in a patient with urticarial vasculitis.

TABLE 162.1

Relationship between vasculitic syndrome and its predominant cutaneous manifestation

Clinical syndrome	Predominant cutaneous morphology
Leukocytoclastic vasculitis	Palpable purpura
Henoch-Schönlein purpura	Retiform purpuric plaques
Hypocomplementemic urticarial vasculitis	Urticarial lesions of long duration that resolve with purpura or ecchymosis
Granulomatosis with polyangiitis (formerly known as Wegener granulomatosis)	Ulcerative nodules, palpable purpura, peripheral gangrene
Polyarteritis nodosa	Subcutaneous nodules, livedo reticularis, ulcerations, peripheral gangrene

BOX 162.2 SYSTEMIC DISEASES ASSOCIATED WITH LEUKOCYTOCLASTIC VASCULITIS (SMALL-VESSEL VASCULITIS)

Other vasculitic syndromes: Granulomatosis with polyangiitis, polyarteritis nodosa, microscopic polyarteritis

Rheumatic disorders: Systemic lupus erythematosus, rheumatoid arthritis, idiopathic inflammatory myopathy, Sjögren syndrome

Infections: Hepatitis C virus infection, hepatitis B virus infection, human immunodeficiency virus infection, infection with β -hemolytic streptococci, subacute bacterial endocarditis

Paraprotein disorders: Cryoglobulinemia (usually mixed, often hepatitis C virus related), macroglobulinemia, hyperglobulinemia

Other disorders: Inflammatory bowel disease, neoplasia (hairy cell leukemia, lymphoma, or rarely solid tumors), cystic fibrosis, bowel bypass syndrome, deficiency of the second component of complement, α_1 -antitrypsin deficiency

Urticarial lesions may also be an early clinical manifestation of lesions that become typical palpable purpura. The spectrum of urticarial vasculitis has also grown, in recent years, to include the presence of lung manifestations characterized by asthma or obstructive lung disease.¹¹ Patients with hypocomplementemic urticarial vasculitis often have or develop obstructive disease, whereas most patients with normal complement levels, chronic urticaria, and vasculitis have little or no systemic involvement.¹²

Vasculitis associated with paraproteinemia

Almost any clinical lesion, from urticarial lesions through palpable purpura to necrosis and ulceration, can occur in patients with an abnormal circulating protein. In patients with cryoglobulins there may be a predilection for acral disease affecting the toes, fingers, ears, and nose; otherwise these patients have lesions and distributions similar to those of patients without a paraprotein. The presence of a paraproteinemia in patients with vasculitis has therapeutic implications; thus almost all patients with chronic or recurrent cutaneous vasculitis should undergo evaluation for a paraprotein, including testing for cryoglobulins and immunofixation electrophoresis. In many of the patients with mixed cryoglobulinemia, a link with hepatitis C virus infection has been noted.¹³ These patients may have noninflammatory occlusive disease or a small-vessel vasculitis. Treatment with interferon

Fig. 162.5 Nonpalpable lesions of hyperglobulinemic purpura in Waldenström hypergamma globulinemia.

alfa-2a and/or ribavirin with or without rituximab has led to disease control in many of these patients.¹⁴

Hyperglobulinemic purpura has been separated from other vasculitides¹⁵ because some of the lesions of hyperglobulinemic purpura are nonpalpable (Fig. 162.5) and do not reveal LCV on biopsy. However, this may indicate that these lesions are early or late manifestations, and in the authors' experience, if the skin biopsy is timed appropriately, the specimens usually reveal LCV. Hyperglobulinemic purpura has recently been associated with Sjögren syndrome and lupus erythematosus. These patients commonly demonstrate the anti-Ro (anti-SS-A) antibody.

Paraneoplastic vasculitis

Cutaneous or systemic vasculitis, or both, have been reported on several occasions in patients who have or have had malignancies.¹⁶ Sanchez-Guerrero and colleagues¹⁷ reported that 11 of a series of 222 patients newly diagnosed with vasculitis of any form had what was judged to be "paraneoplastic vasculitis." In most of these patients (9 of 11), the vasculitis was limited to the small cutaneous vessels and was histologically characterized as LCV. In 3 patients, the vasculitis was the presenting manifestation of neoplasia (squamous cell carcinoma of the esophagus, T-cell lymphoma, and myeloblastic leukemia). A recent report from Northwest Spain^{17b} suggested that the incidence of malignancy is perhaps as high as 3.8% of adult patients.

The occurrence of solid organ malignancies with cutaneous vasculitis has been considered to be rare. However, Podjasek and coworkers¹⁸ identified a group of 17 such patients seen at the Mayo Clinic over a 14-year period. These patients were found through a review of 812 charts, which represents something around a 2% occurrence rate. The vasculitis occurred before the malignancy in 3 patients, concurrently in 3 patients, and after the malignancy in 11 patients. It was not clear from their report whether a paraneoplastic course occurred in any patient. Many of the patients were treated with prednisone and some were treated with immunosuppressive or cytotoxic agents, often successfully.

The mechanisms underlying paraneoplastic vasculitis are unknown. The vasculitis can at times be directly related to tumor treatment, but in many cases the occurrence appears to be coincidental. The exact incidence of neoplasia with vasculitis is not known, and thus extensive evaluation for malignancy cannot be recommended; unexplained symptoms, however, should be investigated. Lymphoreticular malignancies—in particular, hairy cell leukemia and non-Hodgkin B-cell lymphoma—have been the most frequently reported type of neoplasia, but a wide variety of solid tumors also have occurred in patients with vasculitis.^{16,19}

Cutaneous polyarteritis nodosa

Cutaneous polyarteritis nodosa is characterized clinically by nodules, livedo reticularis, ulcerations, or a combination of these lesions (Fig. 162.6).^{20,21} Histopathologically, the lesions are characterized by LCV of the arterioles, often in the subcutaneous tissue, occasionally with a surrounding panniculitis (Fig. 162.7). The nodular lesions must be differentiated from erythema nodosum or other panniculitides. Livedo reticularis can occur with thrombotic disorders of several causes, including acquired disorders such as

antiphospholipid antibody syndrome and inherited thrombophilic disorders including factor V Leiden mutation and methylenetetrahydrofolate reductase polymorphisms. Cutaneous polyarteritis nodosa is generally associated with a good prognosis, but patients with ulcerations tend to have neuropathy more frequently.²¹ A variety of systemic disease associations, including inflammatory bowel disease, rheumatoid arthritis, and paraproteinemia, have been reported in patients with cutaneous polyarteritis nodosa. The cutaneous and systemic forms of polyarteritis nodosa have been linked to exposure to several drugs, including propylthiouracil use and the prolonged use of minocycline.²² Systemic polyarteritis nodosa may manifest skin lesions similar to those of the cutaneous form but shows involvement of muscular arteries in other organs. A more detailed discussion of systemic polyarteritis nodosa is provided in Chapter 155.

Erythema elevatum diutinum

Erythema elevatum diutinum is a rare form of LCV that has its major manifestation in the skin.²³ The lesions begin as red-purple or yellow papules that coalesce to form plaques. The most prominent involvement occurs on the extensor surfaces, such as the knees, elbows, and dorsa of the hands (Fig. 162.8). The only systemic manifestation is arthralgia, which occurs in 20% to 40% of patients. Some of the patients with erythema elevatum diutinum are found to have an immunoglobulin A paraprotein. Histopathologically, the characteristic finding of concentric perivascular fibrosis around the involved vessels is found in longstanding lesions.

Cutaneous vasculitis in patients with rheumatic diseases

Cutaneous vasculitis, as manifested by palpable purpura, urticarial lesions, or ulcerations, is commonly observed in systemic lupus erythematosus,

rheumatoid arthritis, and Sjögren syndrome. The appearance of cutaneous vasculitis is usually associated with active systemic disease.

Cocaine/levamisole-associated vasculitis/vasculopathy syndrome

A recent “epidemic” of vasculitis/vasculopathy syndrome related to the use of levamisole as an adulterant for cocaine has been seen at various medical centers and reported in the medical literature.²⁴ These patients have acral necrotic/purpuric lesions and may have widespread necrotizing livedo or ulcers (Fig. 162.9) along with positivity for perinuclear antineutrophil cytoplasmic antibodies and antiphospholipid antibodies, leukopenia, and thrombocytopenia. Patients have findings of LCV as well as an occlusive vasculopathy on biopsy. Recovery occurs with cessation of levamisole use but recurs if the patient begins to use the product again. The pathogenesis of this process is not understood.

Panniculitides

Erythema nodosum

Erythema nodosum (EN) is a relatively common process that is usually acute and self-limited. The typical clinical presentation is the sudden onset of one or more tender, erythematous nodules on the anterior legs that are more easily palpated than visualized (Fig. 162.10). The eruption is often preceded by a prodrome of fever, malaise, and/or arthralgias. As the lesions age they may develop an ecchymotic appearance. Over a 4- to 6-week period they eventually heal without scar formation. Ulceration of the primary process is rare. Although EN is usually an acute process, patients with chronic or recurrent disease have been described using terms such as *chronic EN*, *EN migrans*, *subacute nodular migratory panniculitis* (Vilanova disease), or *septal granulomatous panniculitis*. Chronic or recurrent EN most commonly occurs in middle-aged women. The disease is often present for several years and is most common on the legs.

Biopsy of characteristic acute lesions is usually not needed to confirm a diagnosis but, when performed, specimens reveal a predominantly septal panniculitis without vascular inflammation but with scattered radial Miescher granulomas within the connective tissue septa. The presence of the granulomas might be predictive of an associated granulomatous disease such as sarcoidosis.

Causative or associated conditions are present in about 50% of patients with EN.²⁵ The associated conditions can be divided into three broad categories: infections, drug exposures, and systemic diseases (usually inflammatory disorders). A partial list of the known associations is given in Box 162.3. The infectious agents associated with EN tend primarily to affect the respiratory or gastrointestinal tract and are most often bacterial or fungal. The drugs most commonly associated with EN are antibiotics and oral contraceptives. Pregnancy, particularly in its second trimester, is a known association, and the EN will recur with subsequent pregnancies or with the administration of oral contraceptives. EN-like lesions may occur in Behçet disease and are accompanied by oral and genital ulcerations, pathergy, uveitis, and/or central nervous system disease or other systemic manifestations. A specific variant of sarcoidosis associated with EN is known as *Löfgren syndrome*.^{25,26} This disorder is an acute, self-resolving process in which EN occurs with bilateral hilar lymphadenopathy, arthritis, and

anterior uveitis. Granulomatous colitis (Crohn disease), regional enteritis, and ulcerative colitis have been associated with EN.²⁷ In patients with inflammatory bowel disease, it appears that the EN parallels the activity of the bowel disorder. At least half of cases of EN are not found to have an associated or underlying process.

Idiopathic neutrophilic lobular panniculitis

Idiopathic neutrophilic lobular panniculitis was formerly known as *Weber-Christian disease* (WCD). Thus in the past a diagnosis of WCD would be given when patients had multiple recurrent subcutaneous nodules with

Fig. 162.10 Erythema nodosum secondary to acute sarcoidosis.

Idiopathic

Drugs

- Antibiotics: penicillin, sulfonamides
- Birth control pills

accompanying fever and a biopsy specimen that revealed a lobular panniculitis with an early neutrophilic infiltrate with fat degeneration, foamy histiocytes, and giant cell formation. However, increasingly, many such patients are found to have other disease associations, and the number of patients with WCD has progressively decreased. White and Winkelmann²⁸ suggest that when patients with WCD are observed, many can be reclassified as having another panniculitic syndrome.

α_1 -Antitrypsin deficiency-associated panniculitis

Not infrequently, patients with panniculitis have a deficiency of α_1 -antitrypsin. Thus, in a study of 96 patients, Smith and associates²⁹ found 15 patients with such deficiency. These patients were more likely to have ulceration and drainage and correspondingly had greater amounts of fat necrosis and elastic tissue destruction. It was suggested that induction of lesions by trauma was more likely in these patients, and thus débridement should be avoided in such patients. They should also be evaluated for pulmonary and liver disease and counseled to avoid smoking; treatment with α_1 -proteinase inhibitor concentrate may be helpful.

Pancreatic panniculitis

Patients with pancreatic diseases may develop subcutaneous fat necrosis (lobular panniculitis) (Fig. e162.4) with accompanying polyarthritides and osseous intramedullary fat necrosis. A variety of pancreatic pathologic changes have been implicated in the development of this process, including pancreatitis, pancreatic carcinoma (acinar cell), pancreatitis secondary to

Fig. e162.4 Pancreatic panniculitis manifesting as erythematous tender nodules on the anterior legs.

Fig. 162.11 Pancreatic panniculitis with extensive necrosis and ghost lipocytes.

cholelithiasis, posttraumatic lesions, pancreatic ischemia, pancreatic pseudocyst, and pancreas divisum (a congenital pancreatic abnormality).³⁰⁻³² The pathogenesis of pancreatic panniculitis is not well understood. It is possible that pancreatic enzymes directly destroy fat and that the inflammation follows, as demonstrated by Dhawan and associates³⁰; however, elevations of pancreatic enzymes, particularly lipase, do not occur in all pancreatic diseases that have been associated with pancreatitis. Histopathologically, there is extensive fat necrosis with a basophilic alteration of lipocytes (Fig. 162.11). Ghost cells with absent nuclei are also common.

Calcifying panniculitis of renal failure

Patients with renal failure often have abnormal calcium and phosphorus metabolism. These patients may develop acute, erythematous, tender, indurated nodules as a manifestation of calciphylaxis, more recently termed *calcific uremic arteriopathy*.³³ The panniculitis lesions can progress to necrosis (Fig. 162.12) and ulceration. The prognosis is poor, and treatment should consist of attempts to correct the calcium-phosphorus imbalance. Parathyroidectomy with or without renal transplantation may be helpful. Recently the use of intravenous sodium thiosulfate or oral cinacalcet has been reported to be of benefit in individual patients and small case series.³⁴

Poststeroid panniculitis

Panniculitis after withdrawal of corticosteroid therapy is a rare entity that seems to be limited to children.³⁵ Patients have been treated with corticosteroids for a wide array of problems, including leukemia, nephrotic syndrome, rheumatic carditis, and encephalopathy. Interestingly, the panniculitis may clear on readministration of the corticosteroids. The pathogenesis of this rare complication is not understood. The histopathologic features of this condition are identical to those of subcutaneous fat necrosis of the newborn, which is characterized by needle-shaped crystals within a histiocytic infiltrate.

Lipoatrophic panniculitis

Several conditions have been described in children that often result in lipoatrophy after the inflammatory reaction. There exists a spectrum that perhaps includes lipogranulomatosis subcutanea (previously known as *Rothman-Makai syndrome*), lipoatrophic panniculitis, lipophagic panniculitis of childhood, subcutaneous fat necrosis of the newborn, and localized lipoatrophy (atrophic connective tissue disease panniculitis).³⁶ These children tend to have multiple erythematous lesions, most commonly on the extremities, that resolve with subcutaneous atrophy. The patients often also

Fig. 162.12 Calcific uremic arteriopathy (calciphylaxis). This patient has a reticulated necrosis.

manifest fever. They may have associated autoimmune phenomena, such as juvenile rheumatoid arthritis, Hashimoto thyroiditis, or diabetes mellitus. There is no known effective therapy, although some patients have responded to oral corticosteroids, oral antimalarial agents, or oral dapsone.

Histiocytic cytophagic panniculitis/subcutaneous panniculitis-like T-cell lymphoma

Histiocytic cytophagic panniculitis was described by Crotty and Winkelmann³⁷ as a chronic histiocytic disease of the subcutaneous fat, with accompanying inflammatory panniculitis, fever, serositis, and "reticuloendotheliomegaly." Craig and coworkers³⁸ have suggested that there are two, perhaps distinct, patterns of disease: one that is benign and is termed *cytophagic histiocytic panniculitis* and one that is malignant and is termed *subcutaneous T-cell lymphoma*. In both instances the hemophagocytic syndrome may occur, but in cytophagic histiocytic panniculitis there is often a response to prednisone and/or cyclosporine. Some of these patients perhaps have Epstein-Barr virus within their lesions. There are some patients who initially appear to have a connective tissue panniculitis, but with time it becomes evident that the correct diagnosis is subcutaneous panniculitis-like T-cell lymphoma.³⁹⁻⁴³ The World Health Organization has recently reclassified subcutaneous panniculitis-like T-cell lymphoma into those with an $\alpha\beta$ T-cell subtype and those with a $\gamma\delta$ phenotype. The $\alpha\beta$ subtype, when it occurs without an associated hemophagocytic syndrome, appears to be steroid responsive and to have an indolent course.⁴⁴ Therefore the diagnosis of subcutaneous panniculitis-like T-cell lymphoma should be reserved only for subcutaneous T-cell lymphomas with CD3+, CD4-, CD8+, and β F1+ immunophenotype ($\alpha\beta$ T-cell subtype).

Lupus erythematosus panniculitis (lupus profundus)

Lupus erythematosus panniculitis (LEP) is a rare cutaneous manifestation of lupus erythematosus (LE) occurring in 1% to 3% of patients with LE.^{45,46} The lesions are tender, red-blue, subcutaneous nodules that may eventually ulcerate. They tend to occur on the face (Fig. 162.13), upper arms, thighs, and/or buttocks. The lesions may underlie a typical lesion of discoid LE. Histopathologic changes include a panniculitis that is both lobular and septal (Fig. 162.14). When the overlying epidermis and/or dermis demonstrate changes of LE, the diagnosis of LEP can be histologically confirmed. The activity of the panniculitic lesion does not seem to follow the course of the systemic disease.

Sclerosing panniculitis (lipodermatosclerosis)

Jorizzo and colleagues⁴⁷ coined the term *sclerosing panniculitis* to describe panniculitis with well-circumscribed, indurated, inflammatory plaques of the lower extremity; others have used the term *lipodermatosclerosis* to

Fig. 162.13 Lupus erythematosus panniculitis manifesting as multiple atrophic, calcified lesions on the arm.

Fig. 162.14 Mixed lobular and septal panniculitis.

Fig. 162.15 Sclerosing panniculitis. (a) Extensive lobular panniculitis with fibrosis. (b) Close-up of characteristic fat microcysts with foci of membranous fat necrosis.

Because sclerosing panniculitis is a manifestation of venous insufficiency, therapy should include the use of support stockings, leg elevation, and rest. Measures for the prevention of phlebitis are also warranted. Low doses of aspirin or other nonsteroidal antiinflammatory drugs (NSAIDs) may be helpful. In patients with factor V Leiden mutation, the use of warfarin or heparin might be beneficial, and in those with a polymorphism of methylenetetrahydrofolate reductase the use of folic acid and other B vitamins might help. Intralesional injection of triamcinolone acetonide may also be beneficial.

Factitial panniculitis

Factitial panniculitis caused by external trauma or the injection of foreign substances is not common but should be considered in patients with unusual clinical or histopathologic features of panniculitis. In traumatic lesions an organizing hematoma may be demonstrated histologically, whereas with injections one encounters refractile bodies or a “Swiss cheese” effect. Occasionally, spectroscopic and/or chromatographic techniques are necessary to identify the causative injected material.

INVESTIGATIONS

Cutaneous vasculitis

The purpose of evaluation is, first, to identify a cause or an associated condition and, second, to assess the presence and severity of systemic involvement.⁴⁹ The evaluation begins with a careful history taking and physical examination. **Box 162.4** presents the basic workup recommended for patients with cutaneous vasculitis. In patients with acute disease in whom there is an obvious cause such as a drug or infection, the evaluation is streamlined and need not assess for all possible causes. Skin biopsy of an early lesion is necessary to confirm the presence of LCV but often is not performed in children with typical lesions.⁸ In patients with chronic disease or those in whom there is not an obvious cause, the workup is more extensive. An assessment for paraproteins is necessary in this group of patients, but evaluation for malignancy is probably not necessary unless there are other symptoms or signs. Immunofluorescence testing of a cutaneous biopsy specimen can be useful when Henoch-Schönlein purpura is considered.

Panniculitis

As in patients with cutaneous vasculitis, the evaluation of patients with panniculitis should include taking a careful history and performing physical

describe this condition. Often the leg looks like an inverted soda bottle due to the sclerosis of tissue around and immediately above the ankle (**Fig. e162.5**). These lesions most frequently occur in women and are usually accompanied by signs of venous insufficiency. Some patients have known prior thrombophlebitis, and evidence of venous insufficiency may be present. Patients with this entity are sometimes found to have a tendency toward thrombophilia, as evidenced by the presence of factor V Leiden mutation or methylenetetrahydrofolate reductase polymorphisms. Histopathologically this disorder is characterized by fat necrosis, sclerosis, and a lobular panniculitis.⁴⁸ Fat microcysts with foci of membranous fat necrosis are also commonly observed in the later stages of the disease (**Fig. 162.15**).

Fig. e162.5 Sclerosing panniculitis characterized by tender, indurated, hyperpigmented plaques overlying the medial malleoli.

examination. The possibility of infection of the upper respiratory tract should be considered, and a throat swab for a rapid streptococcal screening, skin tests for tuberculosis, and a chest radiograph should be obtained. In general, neither inflammatory bowel disease nor infectious enteritis is asymptomatic, and thus it is not necessary to perform endoscopic or radiographic procedures in these patients. Tests for enzymatic abnormalities, such as amylase, lipase, or α_1 -antitrypsin deficiency, should be ordered. The

possibility of a coexistent collagen vascular disease should also be considered.

DIFFERENTIAL DIAGNOSIS

Cutaneous vasculitis

The differential diagnosis of cutaneous vasculitis differs with each clinical lesion. Palpable purpura must be differentiated from traumatic purpura, capillaritis (also known as *chronic pigmented purpura*), insect bites, embolic phenomena, and a variety of infections. Embolic processes that can mimic vasculitis include atheromatous emboli and emboli from a left atrial myxoma. In addition, endocarditis may mimic cutaneous vasculitis.⁴⁹

Urticarial lesions must be differentiated from “garden variety” urticaria, bites, erythema multiforme, and drug eruptions. Ulcerations can occur from noninflammatory vessel occlusion such as atherosclerosis, malignant processes, or bites, or from nonvascular inflammatory conditions such as pyoderma gangrenosum. Livedo reticularis usually occurs with involvement of medium-sized vessels and secondary to atherosclerosis, emboli, or occlusive vasculopathy associated with antiphospholipid antibody syndrome.

Panniculitis

The differential diagnosis of panniculitis involves distinguishing it primarily from insect bites, thrombophlebitis, and cellulitis. Insect bites may be tender, red, infiltrated lesions. The distribution is dependent on the type of bite, and in general the patient is otherwise asymptomatic. Often there is a puncture site within the lesion. Cellulitis rarely manifests as subcutaneous nodules. When the diagnosis is in question, wedge biopsy or deep punch biopsy that includes subcutaneous fat is helpful.

MANAGEMENT

Cutaneous vasculitis

The treatment of cutaneous vasculitis depends on whether there is clinical evidence of systemic disease and how severe the cutaneous disease is. Table 162.2 highlights some of the treatments that might be considered for various cutaneous vasculitic syndromes. The patient with severe systemic necrotizing vasculitis should be treated rapidly and aggressively with systemic corticosteroids and possibly an immunosuppressive agent. Pulsed treatment

BOX 162.4 EVALUATION OF THE PATIENT WITH CUTANEOUS VASCULITIS

History

- Infections?
- Drug ingestion?
- Prior occurrence of one of the associated disorders?
- Any systemic symptoms?

Physical examination

- General appearance
- Vital signs
- Type and distribution of lesions
- Evidence of arthritis?

Skin biopsy

- Routine skin biopsy should be performed on a fresh lesion in all patients
- Immunofluorescence microscopy is optional; may be useful when Henoch-Schönlein purpura is considered

Laboratory studies

Necessary

- Complete blood cell count
- Urinalysis
- Chest radiograph
- Tests for collagen vascular diseases: antinuclear antibody, anti-Ro (SS-A), rheumatoid factor
- Hepatitis C antibody, hepatitis B surface antigen
- Paraproteins: cryoglobulin assay, immunofixation electrophoresis
- Antineutrophil cytoplasmic antibodies

When appropriate or under special circumstances

- Total hemolytic complement
- Circulating immune complexes
- Erythrocyte sedimentation rate and/or C-reactive protein level
- Blood cultures

TABLE 162.2

Treatment of cutaneous vasculitis based on syndrome

Syndrome	First choice	Alternative choices	Comments
Hypersensitivity vasculitis	Identify and remove the antigen. Consider dietary therapy. Treat any associated disorder.	Colchicine, dapsone, immunosuppressive agent (methotrexate, azathioprine, etc.), rituximab, corticosteroids	A thorough evaluation is needed to exclude other vasculitic syndromes that may manifest as palpable purpura.
Henoch-Schönlein purpura	Observation	Corticosteroids, immunosuppressive agent, or both	There are no data demonstrating that treatment alters the outcome. Often this condition is self-limiting. Hypertension, preeclampsia in women, and renal failure are possible long-term sequelae.
Urticarial vasculitis—normocomplementemic	Antihistamines	Colchicine, dapsone, corticosteroids, immunosuppressive agents, intravenous immunoglobulin	Chronic urticaria, particularly when associated with vasculitis, is probably an immune-mediated disorder.
Urticarial vasculitis—hypocomplementemic	Dapsone, corticosteroids, immunosuppressive agents	Intravenous immunoglobulin	This disorder is difficult to treat. Associated pulmonary disease may occur and there is no known effective therapy.
Vasculitis with hepatitis C virus	Interferon with or without ribavirin	Corticosteroids	Suppression of the viral load may decrease the manifestations of vasculitis.
Vasculitis in a patient with B-cell lymphoma (or a history of lymphoma)	Colchicine, dapsone	Rituximab, intravenous immune globulin	
Cutaneous polyarteritis nodosa	Corticosteroids or immunosuppressive agents (methotrexate or azathioprine)	Intravenous immunoglobulin	Although there is a primary focus on the skin, patients may develop ulcers or may have associated inflammatory bowel disease, mononeuritis multiplex, and/or arthritis.
Erythema elevatum diutinum	Dapsone	Corticosteroids	

with either methylprednisolone or cyclophosphamide can result in rapid control of the disease.

Patients with chronic cutaneous vasculitis tend to be frustrated and frequently desire treatment for symptomatic relief or for cosmetic reasons. In some cases, small recurrent purpuric lesions with superficial ulceration can compromise the patient's ability to work. In patients with acute disease such as Henoch-Schönlein purpura, no treatment may be necessary other than agents for symptomatic relief.

It is important to identify and remove any offending antigen that may be present. Some examples are ingestants such as a drug, food, or food additive that can be avoided. Lunardi and colleagues⁵⁰ described five patients with chronic cutaneous vasculitis in whom dietary factors were found to be causative. Some patients with paraneoplastic vasculitis whose tumors are removed experience resolution of the vasculitis. Patients with paraproteinemia may be good candidates for treatment with an immunosuppressive agent to suppress the formation of the abnormal protein, and in the case of hepatitis C virus-associated cryoglobulinemic purpura, interferon alfa-2a with or without ribavirin and with or without rituximab has been useful.^{18,51} Patients with erythema elevatum diutinum seem to respond extremely well to oral dapsone therapy. Finally, patients with a lymphoma or a history of a lymphoma may respond to rituximab.

Patients without an identifiable cause or associated phenomenon who require therapy can be treated with a variety of agents. A therapeutic ladder can be designed from which treatments can be selected sequentially until an appropriate and effective agent is identified. Because the postulated mechanism for cutaneous vasculitis involves immune complex-mediated disease, complement activation, chemotaxis of polymorphonuclear leukocytes, lysosomal release, and resultant cell destruction modulated by vasoactive substances, agents that interfere with any of these processes may be beneficial. Agents such as antihistamines, NSAIDs, antimalarials, and sulfones have been reported to be therapeutic in individual cases, but they have not been uniformly effective in the authors' experience. Corticosteroids, if given at a sufficiently high dosage, are almost always effective. In open-label trials, colchicine was effective in 75% to 80% of patients with cutaneous vasculitis⁵²; however, in the only published double-blind, placebo-controlled trial, colchicine failed to demonstrate efficacy.⁵³ In the authors' view, that trial was compromised by biases that favored a response in the placebo group. Immunosuppressive agents such as azathioprine, cyclophosphamide, methotrexate, mycophenolate mofetil, and cyclosporine are also often effective. Recently developed biologic agents such as rituximab have benefited some patients.⁵⁴

The burning or itching of the lesions most often irritates patients with urticarial vasculitis. The patient should be treated first with antihistamines. Histamine 1 (H₁) receptor antagonists can be combined with H₂ antagonists, but the dosages required often result in drowsiness. In some cases, the use of doxepin, which has effects on both H₁ and H₂ receptors, is effective. Finally, the newer, less-sedating agent cetirizine or nonsedating agents such as fexofenadine or loratadine can be used during waking hours and a soporific agent given before retiring.

Panniculitis

There are few randomized, controlled clinical trials to guide treatment decisions in the panniculitis group of disorders. The treatment of EN and other panniculitides first involves the search for a causative disease and its treatment if present. In the absence of a treatable disorder, therapy is symptomatic. Acute EN is often self-limited; thus nontoxic therapies are advised. Bed rest and leg elevation are very helpful in controlling symptoms. In patients who need to be ambulatory, use of support stockings or tights may be helpful. Aspirin or other NSAIDs may be effective. Sometimes, however, treatment with aspirin does not produce results before toxicity is reached, and oral indomethacin (25 to 75 mg/day) is therefore recommended.

In patients with chronic EN or frequent recurrences, oral potassium iodide (300 to 900 mg/day) has been useful in open clinical trials. When the drug is stopped or the dose is lowered, the disease often relapses, only to respond again with reinstitution of therapy. Other therapies that may be considered are oral corticosteroids, colchicine, hydroxychloroquine, or an immunosuppressive agent. Cyclosporine has been used successfully in some patients. One adjunctive therapy that can be helpful is intralesional injection of triamcinolone acetonide.

There is no specific therapy for patients with idiopathic neutrophilic lobular panniculitis. Reports have centered on the use of antiinflammatory agents (aspirin, other NSAIDs), oral corticosteroids, antimalarial agents, and immunosuppressive agents (cyclophosphamide and cyclosporine). In addition, colchicine, dapsone, and potassium iodide may be effective in some individual cases. There is no information regarding the role of biologic therapy in these patients.

Patients with $\alpha\beta$ subcutaneous panniculitis-like T-cell lymphoma who do not have an associated hematophagocytic syndrome are often steroid responsive, and the prognosis is generally good. Those with a $\gamma\delta$ phenotype have a more aggressive form and referral to an oncologist is recommended.

Patients with LEP may respond to antimalarial agents or to intralesional injections of triamcinolone. Corticosteroids and/or immunosuppressive agents are rarely necessary in LEP.

CONCLUSION

The cutaneous vasculitides and panniculitides form a wide array of syndromes that often can be separated on the basis of clinical features, associated disorders, and/or histopathologic findings. The newest lesion should be sampled. Evaluation for an underlying process should include investigation for ingestants, infections, malignancy, and autoimmune disorders. In the absence of an underlying disease, treatment is aimed at control of the inflammatory reaction with NSAIDs, corticosteroids, dapsone, potassium iodide, antimalarial agents, colchicine, or cytotoxic or immunosuppressive agents.

163 Cryoglobulinemia

■ ALESSANDRA DELLA ROSSA ■ ANTONIO TAVONI ■ STEFANO BOMBARDIERI

- Cryoglobulinemia is characterized by the presence in the serum of one or more immunoglobulins that precipitate at temperatures below 37°C and redissolve on rewarming.
- Three types of cryoglobulins are recognized: type I, an isolated monoclonal immunoglobulin; type II, immunoglobulin G (IgG) and an IgM rheumatoid factor (RF) of monoclonal origin; and type III, IgG and a polyclonal IgM RF. The presence of Types II and III is considered mixed cryoglobulinemia.
- This disease predominantly affects middle-aged women. A hepatitis C virus infection is the cause in the majority of mixed cryoglobulinemia cases (60%-90%).
- Histologically cryoglobulinemia is a small-vessel leukocytoclastic vasculitis.
- Clinically, dependent purpura is evident in almost all patients. Other common features include weakness, arthralgias, liver involvement, Raynaud phenomenon, and multiplex mononeuritis.

HISTORY

The term *cryoglobulinemia* refers to the presence in the serum of one or more immunoglobulins that precipitate at temperatures below 37°C and redissolve on rewarming.

According to Brouet and associates,¹ the cryoglobulins can be subdivided into three subgroups: type I contains an isolated monoclonal immunoglobulin, type II comprises immunoglobulin G (IgG) and an IgM rheumatoid factor (RF) of monoclonal origin, and type III comprises IgG and a polyclonal IgM RF.

Type I cryoglobulins are frequently of the IgG isotype; less frequently they may be composed of IgM, IgA, or light chains.² Type I cryoglobulinemia is frequently associated with immunoproliferative disorders.

Mixed cryoglobulins (types II and III) are composed of IgG, plus an IgM (rarely of either IgA or IgG) with RF activity. They represent up to 80% of all cryoglobulins and are generally present in lower concentrations than monoclonal cryoglobulins. Mixed cryoglobulinemia (MC) has been described in association with chronic infections and autoimmune disorders.³

In 1966, Meltzer and Franklin described for the first time a syndrome characterized clinically by the triad of weakness, arthralgias, and Raynaud phenomenon and by the presence of mixed cryoglobulins without any known precipitating factor; this condition was termed *essential MC*.²

However, the frequent finding of liver involvement in patients with MC, which is much less common in other immune complex-mediated diseases, suggested the hypothesis that an environmental factor, possibly a hepatotropic virus, might be the actual trigger of the disease. An association with the hepatitis B virus (HBV) was suggested, but this was not confirmed by subsequent studies, in which HBV antigenemia was only occasionally detected in individuals with antibodies against the HBV surface antigen.⁴

Studies in the 1990s on large series of patients with MC definitively eliminated HBV as a causative agent in most cases of MC, and the hypothesis of a hepatotropic virus as a causal agent became less convincing.⁵

Subsequently, however, the identification of hepatitis C virus (HCV) as the main causative agent of non-A, non-B hepatitis⁶ provided fresh support for this hypothesis. Because HCV is a hepatotropic virus that can cause

chronic infection with liver involvement, its prevalence was evaluated in a small series of patients with MC. With the use of first-generation tests, antibodies against HCV were initially demonstrated in 30% to 54% of all patients with MC.⁷⁻⁹ With newer tests, the prevalence was found to be even higher, ranging from 70% to 100%. Increasing evidence suggested that this association also has pathogenetic significance. In particular, the demonstration of the specific concentration of HCV in type II cryoglobulins, immunohistochemical evidence of HCV-associated antigens in vasculitic skin biopsy specimens, and the presence of HCV RNA in serum and plasma samples and of HCV infection in the peripheral mononuclear cells of patients with MC all lend support to the etiopathogenetic role of HCV in MC. Because this role has been universally accepted, the term *essential MC* should be dropped, and in the majority of cases the disease should be referred as to *HCV-related MC*.^{2,10} HCV-negative MC accounts for about 5% to 10% of cases.¹¹

EPIDEMIOLOGY

The prevalence of MC is not homogeneous across countries; it is more frequent in southern Europe than in northern Europe or North America. The geographic distribution of MC seems to be closely related to the endemic presence of HCV infection. Among the different HCV genotypes, genotype 2a has been described to be more frequent in patients with MC than in chronic HCV carriers without MC. Different prevalences of serum cryoglobulins, ranging from 19% to 50%, have been reported in HCV-infected patients. Clinical overt cryoglobulinemic syndrome seems to be evident in 15% to 30% of these subjects and in 5% to 10% of all HCV-infected patients.¹²

CLINICAL FEATURES

MC shows a slow progression with periods of exacerbation and remission and rare acute flares.

Purpura

Purpura almost always occurs in patients with MC, often as the presenting feature. It is characteristically nonpruritic, is intermittent, and involves the lower extremities because venous stasis favors the precipitation of cryoglobulins. In widespread and severe forms of the disease, however, it can also involve the abdomen and chest (Figs. 163.1 and 163.2). An association of leg ulcers with purpura is the presenting symptom in 22% of patients (Fig. 163.3). Histologically, it is characterized by dermal vasculitis with a variable degree of involvement of the subcutaneous interstitium.⁴

Raynaud phenomenon

Raynaud phenomenon, usually mild and nonnecrotizing, is present in 25% of patients at diagnosis.

Joint involvement

Arthralgias are present in the majority of cases and usually recur intermittently during the course of the disease. Occasionally, a frank arthritis can occur.⁴ During chronic HCV infection two different clinical subsets of arthritis have been described to occur: (1) a monoarticular or oligoarticular intermittent arthritis involving large and medium-sized joints (almost always with the presence of cryoglobulins), and (2) a polyarticular symmetric arthritis closely resembling rheumatoid arthritis (RA). Differentiating

Fig. 163.1 Patient with cryoglobulinemic purpura involving the lower limbs. The right limb is more involved than the left because venous stasis favors the precipitation of cryoglobulins (the patient had venous insufficiency on the right side).

Fig. 163.2 In widespread cutaneous vasculitis the purpura involves limbs, abdomen, and chest. This photograph shows the dorsum of a patient with diffuse purpura.

between true RA and HCV-related RA-like arthritis can be particularly challenging because there are no reliable clinical parameters that can distinguish between the two conditions. In general, HCV-related arthritis is less serious and nonerosive than classical RA. Recently, anti-cyclic citrullinated peptide antibodies, which are always absent in MC, have been suggested as a useful tool in distinguishing between the two disorders.^{13,14}

Renal involvement

Renal involvement is one of the most serious complications of MC and affects approximately one third of patients. Histologically, it almost

Fig. 163.3 Skin ulceration is the final result of severe cutaneous vasculitis.

invariably takes the form of type I membranoproliferative glomerulonephritis with a varying degree of interstitial and vascular damage.¹⁵ Clinically, renal involvement ranges from isolated proteinuria to nephritic syndrome. The disease course is generally characterized by periods of remission and exacerbation, and if not adequately treated, the renal disease eventually leads to renal failure in 14% of cases.^{16,17}

Peripheral nerve involvement

Another common feature in patients with MC is peripheral neuropathy. However, the real frequency of this manifestation is often underestimated, owing to its smoldering clinical course. Subjective symptoms suggesting peripheral neuropathy were present in over 90% of patients with MC,¹⁸ whereas objective manifestations as well as sensory motor conduction velocity abnormalities were detected in half the patients. There were electrophysiologic abnormalities in 82%. Pure motor neuropathy is a rarer finding (about 5%) but, when present, is a disabling condition.

The nerve injury may have a number of underlying causes, including immunologically mediated demyelination, vasculitis, or occlusion of the vasa nervorum by cryoglobulin precipitation. Histologic studies have shown inflammatory vessel damage with axonal degeneration. The correlation found between serum cryoglobulin levels and various neurologic findings suggests that an immune complex-mediated mechanism might be responsible for this nerve damage.^{2,10,16}

Liver involvement

Liver involvement is present in more than two thirds of patients with MC and is predominantly revealed on biochemical testing. Clinically, it is generally asymptomatic and laboratory evidence of cell damage is usually mild or absent. However, the correlation between clinical liver disease and histologic findings is low, because the latter shows in all instances various degrees of periportal inflammation, with fibrosis, architectural derangement, and evidence of cirrhosis in one third of cases.^{2,4}

Lymphoproliferative disorders

HCV infection, independent of concomitant MC, carries an increased risk of development of lymphoma,¹⁸ but this risk is higher in patients with HCV-positive MC syndrome.¹⁹ Some of these cases appear to be highly responsive to antiviral therapy, which provides clinical evidence for a pathogenetic association. HCV-associated lymphomas represent a variety of histologic subtypes, most frequently non-Hodgkin B-cell lymphomas.¹⁸ MC is frequently associated with a benign lymphoproliferative disorder that takes the form of distinct lymphoid infiltrates with B cells bearing surface monoclonal RF (IgMκ) in the portal tracts, spleen, and bone marrow. This disorder, which is responsible for the monoclonal RF in type II cryoglobulins, can evolve in 5% to 10% of patients to frank non-Hodgkin B-cell lymphoma. The risk of developing lymphoma is about 35 times higher in patients with MC than in the general population. Comparison of North American and European series show a clear-cut south-north gradient of prevalence

(reflecting the prevalence of HCV infection), which suggests the intervention of further environmental and/or genetic factors.²⁰

In clinical practice it is possible to observe a sudden decrease or disappearance of serum cryoglobulins or RF, sometimes associated with abnormally high levels of C4, as the presenting symptom of complicating B-cell malignancy.²¹ In addition, a low level of γ -globulin in the setting of HCV-related MC syndrome could predict the diagnosis of Non-Hodgkin lymphoma.²²

Hyperviscosity syndrome

Although increased blood viscosity and reduced blood filtration can be demonstrated in a high percentage of patients with MC, a frank hyperviscosity syndrome is relatively uncommon.^{23,24}

Other manifestations

Other manifestations are dryness of eyes and mouth, bilateral parotid swelling, generalized lymphadenopathy, recurrent abdominal pain, and central nervous system involvement.⁴ In some patients with acute abdomen, laparoscopy discloses a vasculitis of the small mesenteric vessels. Lung involvement has been frequently observed, particularly at the level of the small airways and the pulmonary interstitial spaces.²⁴⁻²⁶ In rare instances patients with MC have cardiovascular involvement with coronary vasculitis, heart failure, and pericarditis²⁷ or isolated gynecologic involvement with vasculitis of the female genital tract.²⁸

OUTCOME

Mortality

Patients with MC have higher mortality rates than the general population.^{29,30} Table 163.1 shows the acute causes of death in patients with MC, the most frequent being renal involvement and widespread vasculitis (most often involving the gastrointestinal tract). Other frequent causes of death are liver involvement and infections. In a significant number of cases, the cause of death remains unknown.²⁹

On the whole, research data on mortality in patients with MC give heterogeneous results, which might be explained by methodologic differences, such as differences in the stage of disease in the patients recruited, time of enrollment, and length of follow-up. However, a number of prognostic factors have been almost invariably associated with a higher mortality; in particular, increasing age, renal involvement, intestinal vasculitis, more severe vasculitis, immune-suppressive treatment, and certain types of cryoglobulins are generally associated with poorer outcome.^{30,31} By contrast, the presence of some clinical features, such as sicca syndrome³⁰ and the use of antiviral agents, has been found to be associated with a better outcome.³¹

■ TABLE 163.1

Acute causes of death in mixed cryoglobulinemia

Mortality rate 16%-66%	
Acute cause of death	%
Stroke	5-25
Hepatocellular carcinoma	10-12
Liver involvement	13-18
Lymphoma	13-21
Pulmonary involvement	10-21
Renal involvement	21-33
Gastrointestinal involvement	12.5
Infection	25-26
Vasculitis	13-31
More than one cause	25-36
Miscellaneous	25
Unknown	18-43

INVESTIGATIONS

The key laboratory parameters for the diagnosis of MC as specified in the preliminary classification criteria for cryoglobulinemic vasculitis³² are (1) the presence of cryoglobulins, (2) the presence of RF, (3) reduced serum levels of C4, and (4) the presence of a serum monoclonal component (Box 163.1).

The laboratory hallmark of MC is the presence of type II or type III cryoglobulins with RF activity. High levels of circulating immunocomplexes and low levels of complement (primarily via activation of the classical pathway) are characteristic findings in MC. Patients with MC may have a monoclonal component in their sera, usually IgM κ ; this reflects the presence of clones of lymphoid cells in the portal tracts of the liver, spleen, and bone marrow.

Detection of cryoglobulins

A 20-mL blood sample should be stored at 37°C until completely coagulated, centrifuged at 37°C at 2500 rpm for 5 minutes, and then stored at 4°C for 1 week. A white precipitate in the bottom of the tube indicates the presence of cryoglobulins. When the tube is rewarmed to 37°C, the precipitate will dissolve.

To quantify the amount of cryoglobulins present in the serum sample, cryocrit should be determined. Briefly, the serum is centrifuged at 2500 rpm in a graduated tube at 4°C and the percentage of cryoglobulins is calculated.

To characterize the cryoglobulins, a variety of immunologic methods can be performed, although immunodiffusion and immunofixation are the methods of choice for the typing of cryoglobulins and for the accurate assessment of clonality. Combining the two procedures may be particularly helpful in determining the oligoclonality of each component of the complex.³³

BOX 163.1 PRELIMINARY CLASSIFICATION CRITERIA FOR CRYOGLOBULINEMIC SYNDROME

Satisfied if findings are positive on at least two of the three items (questionnaire, clinical, laboratory).

The patient must test positive for serum cryoglobulins on at least two determinations at ≥ 12 -week interval.

(i) Questionnaire item: at least two of the following:

- Do you remember one or more episodes of small red spots on your skin, particularly involving the lower limbs?
- Have you ever had red spots on your lower extremities that leave a brownish color after their disappearance?
- Has a doctor ever told you that you have viral hepatitis?

(ii) Clinical item: at least three of the following four (present or past)

- Constitutional symptoms
 - Fatigue
 - Low-grade fever (37°-37.9°C for >10 days with no cause)
 - Fever (>38°C) with no cause
 - Fibromyalgia
- Articular involvement
 - Arthralgias
 - Arthritis
- Vascular involvement
 - Purpura
 - Skin ulcers
 - Necrotizing vasculitis
 - Hyperviscosity syndrome
 - Raynaud phenomenon
- Neurologic involvement
 - Peripheral neuropathy
 - Cranial nerve involvement
 - Vasculitic central nervous system involvement

(iii) Laboratory item: at least two out of the following three (present)

- Reduced serum C4 level
- Presence of serum rheumatoid factor
- Presence of a serum monoclonal component

Detection of rheumatoid factor

RF may be detected by means of either enzyme-linked immunosorbent assay or laser nephelometry.³⁴

Detection of C3 and C4

Antigenic analysis of complement proteins makes use of several tests, such as electrophoresis, immunofixation, immunoelectrophoresis, and nephelometric and immunoturbidimetric quantification. At present, laser nephelometric and immunoturbidimetric analysis are the most commonly employed techniques.³⁵

Detection of hepatitis C virus

Anti-HCV antibodies can be detected in the sera of cryoglobulinemia patients by means of commonly employed immunoassays, immunoblot assays, and, more recently, immunochromatography-based rapid tests. Qualitative and quantitative HCV nucleic acid assays in routine use are based on polymerase chain reaction, branched DNA signal amplification, and transcription-mediated amplification. In addition, assays for HCV genotyping are available, based variously on direct sequencing, reverse hybridization to genotype-specific oligonucleotide probes, and restriction fragment length polymorphism analysis.³⁶

DIFFERENTIAL DIAGNOSIS

Systemic vasculitides

HCV infection may be associated with different types of systemic vasculitides. Polyarteritis nodosa (PAN), although most frequently associated with hepatitis B infection, in a limited number of cases is associated with HCV infection. However, because the prevalence of this infection among PAN patients is low (5% to 10%), the significance of the association is unclear. Moreover, in a small number of patients with PAN, cryoglobulins are also detectable, and this makes the differential diagnosis with MC even more difficult. At presentation, patients with PAN more often have life-threatening systemic vasculitis, malignant hypertension, cerebral angiitis, and ischemic abdominal pain than do patients with MC. Moreover, kidney and liver microaneurysms involving the medium-sized vessels are a hallmark of PAN, whereas small-vessel involvement occurs in MC. Finally, peripheral nerve involvement almost always takes the form of a severe multifocal sensorimotor neuropathy in PAN, whereas distal moderate sensory neuropathy is more frequent in MC.³⁶

Leukocytoclastic vasculitis has been claimed to be associated with HCV infection. Whether this condition is a separate entity or represents an incomplete form of cryoglobulinemia is an unresolved issue. However, the presence of HCV infection in a patient affected by leukocytoclastic vasculitis makes the search for cryoglobulins mandatory.³⁷

Sjögren syndrome

MC and Sjögren syndrome share a number of clinical and serologic features. The prevalence of HCV infection among European patients with primary Sjögren syndrome ranges from 5% to 19%. A small number of patients with MC have anti-Ro/SSA and anti-La/SSB antibodies. Therefore, at least in some instances, a true overlap between the two conditions may exist. In the other cases, differentiating between the two disorders can be unusually difficult. Moreover, it should be stressed that HCV is a sialotropic virus and can cause a true Sjögren syndrome secondary to the infection, even in the absence of cryoglobulins. Features distinguishing between the primary disorder and HCV-related Sjögren syndrome might include a lower prevalence of symptoms of dryness, a significant increase in the prevalence of liver involvement, cryoglobulinemia and hypocomplementemia, a lower prevalence of anti-Ro/SSA and anti-La/SSB autoantibodies, and a milder expression of lymphocytic infiltrates on the salivary glands in HCV-positive patients.^{13,38,39} Recently, the new diagnostic criteria for primary Sjögren syndrome have included HCV infection as an exclusion criterion.⁴⁰

ETIOPATHOGENESIS

MC is a complex disorder with a broad spectrum of clinical manifestations representing an interaction between autoimmune disorders, immune complex-mediated disorders, and lymphoproliferative processes. It is now

clear that HCV plays a central role in the etiopathogenesis of MC.^{2,10,20} Vasculitic lesions are not identical in different organs as far as their pathogenetic mechanisms are concerned. Whereas palpable purpura results from the deposition of complexes of HCV, IgM RF, IgG, and complement components, which are all easily detectable in cutaneous vasculitis, HCV-related proteins are found less often in the kidney and have never been demonstrated in peripheral neuropathy.^{41,42}

HCV, like other RNA viruses, is characterized by a high degree of genetic heterogeneity.² Mutation of HCV during replication favors the escape from the immune system and the persistence of the virus in the host. Chronic HCV infection represents, in turn, a chronic stimulus for the immune system and is one of the main pathogenetic steps in MC. The mechanism leading to the formation of autoantibodies during HCV infection remains obscure. HCV recognizes different binding molecules on the cell surface that are not completely identified. Among them, the most known are CD81, scavenger receptor class B type I and low-density lipoprotein receptor.⁴³ The engagement of HCV with CD81 lowers the B-cell threshold for polyclonal activation, which leads to the formation of autoantibodies and cryoglobulins; however, other factors must also be involved because a large proportion of patients with autoantibodies do not have cryoglobulins. A different mechanism involving intracellular B-lymphocyte infection by HCV seems to underlie HCV-associated monoclonal gammopathy and non-Hodgkin B-cell lymphoma.²⁰

After the initial activation, the continuous exposure to antigen pressure may result in a positive selection of B cells with the emergence of a B-cell population producing a monoclonal IgM rheumatoid factor. These B clones can be found within peripheral blood, bone marrow, and liver of patients with HCV infection; their presence is usually considered as an indolent lymphoproliferative disorder that evolves into a frank malignant lymphoma in a minority of cases.²⁷

The monoclonal IgM molecules secreted by B-cell clones have the peculiarity of bearing a cross-reacting idiotype called WA that binds immunoglobulins directed against anti-HCV core proteins.⁴⁴ A recent study demonstrated that WA B cells can be detected not only in all patients with cryoglobulinemic vasculitis but also in nearly 10% of asymptomatic patients with HCV infection. This discovery suggests that WA B cells may be a marker for the development of cryoglobulinemic vasculitis and for B-cell lymphomas in patients with HCV infection.⁴⁵

Although many steps forward have been made in the knowledge of cryoglobulinemic vasculitis, several aspects of its etiopathogenesis have yet to be clarified, for example, why only some HCV-infected patients develop the cryoglobulinemic syndrome. Recent studies suggest that the host's genetic background plays an important role in determining the susceptibility to cryoglobulinemic vasculitis of some HCV-infected patients. On the basis of this hypothesis some investigators focused their attention on this aspect. They established that the abnormal presence of large immune complexes in MC may be due either to the reduced uptake of immunoglobulins by the reticuloendothelial system or to the excessive production of immunoglobulins by B cells, so they analyzed allelic variants of the low-affinity Fcγ receptor (FcγR) genes and of BAFF promoter. Indeed, low-affinity FcγRs mediate the clearance of circulating cryoglobulins, whereas BAFF, a tumor necrosis factor-α family member, regulates immunoglobulin secretion and B-cell differentiation and survival. From this study no significant differences emerged in the distribution of FcγR genotypes, whereas a greater prevalence of BAFF promoter's T-allele homozygosity was observed in patients with cryoglobulinemic vasculitis than in HCV-infected patients without cryoglobulinemic syndrome. It has been observed that T allele is associated with elevated serum BAFF levels and with the presence of cryoglobulinemic vasculitis.⁴⁶ The host immune response against HCV is not always protective against infection; indeed, viral clearance is not associated with an immunization against reinfection. Immune response in long-term HCV carriers seems to exert a selective pressure on the virus that favors the emergence of viral strains more prone to escape from it. In particular, a substantial divergence between humoral and cell-mediated response to the virus has been unveiled; humoral response is responsible for extrahepatic manifestations and seems to be of no effect in controlling infection. Cell-mediated immune response is of greater importance in the production of antiviral cytokines but seems also to have a role in cytotoxic damage.⁴⁷ In this regard, recently a substantial divergence in cytokine production has been claimed between individuals with HCV infection not associated with cryoglobulinemic syndrome and those with HCV-related cryoglobulinemic vasculitis. In particular, an emerging role for chemokines and type 1 cytokines in the pathophysiology of this vasculitis has been claimed.^{48,49}

The possible etiopathogenesis of MC may be summarized as follows. Among the different possible noxious agents, HCV either alone or in combination with other still unknown factors plays an important role.

Autoimmunity may be a virus-triggered epiphenomenon perpetuated by a variety of factors, including genetic susceptibility, environmental factors, and host and viral factors (e.g., genotype, superinfection with unrelated strains, escape from the immunologic system). The persistence of the virus represents a continuous challenge for the host, and the chronic stimulation of the immune system on the one hand triggers the appearance of autoantibodies through molecular mimicry or other unidentified mechanisms and on the other hand favors the emergence of clones protected against apoptosis; in this way, the pathway of autoimmunity is possibly maintained through a vicious cycle.^{2,10,13} The vascular deposition of immunocomplexes composed of cryoglobulins, with the involvement of viral markers and autoantigens, is responsible for the organ damage observed in MC and in the vasculitis associated with HCV infection. HCV acts as a long-term stimulus on the immune system and infects blood mononuclear cells. Monoclonal or polyclonal B-cell expansion is the most important consequence of this process. Autoantibody production is another result. The activation of oncogenes leads to the emergence of clones protected against apoptosis. This, as previously mentioned, possibly favors the persistence of autoreactive clones and the promotion of lymphoproliferative disorders.^{2,10,11,20,43,47}

MANAGEMENT

MC is a complex multisystem disease. The treatment of this disorder is still a challenge, and different specialists should ideally cooperate to get a better result. The three main aims of any rational therapeutic approach are to eradicate HCV (etiologic therapy), to limit or suppress B-lymphocyte proliferation (pathogenetic therapy), and to ameliorate symptoms and reduce the damage caused by circulating immune complexes (symptomatic therapy).^{27,50} Treatment should be tailored to the individual patient focusing on the clinical history, disease manifestations, possible comorbidities, and previous therapies.^{42,43,47,50}

In cryoglobulinemic patients with life-threatening manifestations (abdominal vasculitis, hemorrhagic alveolitis, hyperviscosity syndrome, and sometimes acute motor neuropathy and rapidly progressive glomerulonephritis) the first-line intervention is a high dose of corticosteroids and plasmapheresis. Concomitant immunosuppressive therapy with cyclophosphamide might be needed to prevent a cryoglobulin rebound after plasmapheresis.^{2,47,50} The possible persistence or onset of cryoglobulinemic vasculitis in patients with persistently negative serum HCV RNA findings suggests that the autoimmune process can become independent of viral triggering and play a predominant pathogenetic role in some disease stages. Therefore antiviral therapy cannot be considered as a first step in more severe cases.^{47,50} Rituximab was recently used successfully in patients with cryoglobulinemic syndrome and severe vasculitis refractory to conventional therapies.^{51,52}

The common manifestations of severe cryoglobulinemic vasculitis are skin ulcers, peripheral neuropathy (motor or sensory neuropathy refractory to symptomatic therapy), and active glomerulonephritis. In these cases the best therapeutic option is rituximab; it destroys CD20+ cells, which may harbor HCV and play an important pathogenetic role in cryoglobulin

production. Indeed, rituximab decreases serum cryoglobulin and RF levels and increases C4 levels with the disappearance of bone marrow B-cell clonal expansion. Glomerulonephritis responds to rituximab within the first 3 months; skin ulcers usually improve within 3 months, but complete healing requires longer. Both sensory and motor neuropathy improve within 1 to 5 months with stable or improved electromyographic findings.⁵⁰ Rituximab can increase HCV viral load but without leading to significant liver impairment; it has been given to cryoglobulinemic vasculitis patients with liver cirrhosis and has led to an improvement in both MC symptoms and liver function.⁵³ By contrast, it may induce a severe reactivation of HBV, so it should be used in patients positive for hepatitis B surface antigen and in occult HBV carriers (patients with anti-hepatitis B core antigen antibodies) only when strictly needed and in combination with antiviral therapy.⁵⁴ The duration of the response to a single cycle of rituximab is difficult to define; long-term responses (more than a year) have been observed most frequently, and retreatment with rituximab after relapses has proved to be effective in most cases.⁵⁰

It has recently been suggested that patients with serious clinical manifestations may receive a combination therapy consisting of rituximab and synchronous or metachronous administration of antiviral therapy. This approach seems to reduce the time to clinical remission and to be more effective than the standard therapies.^{54,55} Antiviral therapy remains a cornerstone in the management of cryoglobulinemic vasculitis in HCV-related cases, and it should be used in patients in more stable condition, particularly those with nonsevere manifestations of cryoglobulinemic vasculitis, such as constitutional features, purpura or arthritis, and very mild renal and neurologic features. The current standard antiviral treatment is the combination of pegylated interferon- α (PEG-IFN- α) and ribavirin. The decision to treat patients with chronic hepatitis C depends on multiple factors including a precise assessment of the severity of liver disease, the presence of absolute or relative contraindications to therapy, and previous treatment failure or intolerance. The HCV genotype is systematically determined before treatment because it determines the duration of treatment (up to 48 weeks for HCV genotype 2 or 3 and 72 weeks for 1 or 4)⁵⁴ as well as the dose of ribavirin.⁵⁵⁻⁵⁸ Treatment with PEG-IFN- α combined with ribavirin led to a sustained antiviral response in 41% to 54% of patients infected with HCV genotype 1 and approximately 80% of those infected with HCV genotypes 2 and 3.⁵⁹ When antiviral therapy is not effective, is contraindicated, or is not tolerated, treatment with rituximab should be considered.⁵⁰⁻⁵²

In the future the treatment of HCV-associated cryoglobulinemic vasculitis may be improved by the administration of an antiviral triple therapy in which the standard PEG-IFN- α and ribavirin may be combined with one of the new protease inhibitors (telaprevir or boceprevir), especially in patients infected by HCV genotype 1.^{56,43}

The treatment of non-HCV-related cryoglobulinemic vasculitis usually is similar to that of other vasculitis, with steroids and immunosuppressive drugs used in most severe cases. In these cases treatment with rituximab also seems effective.^{59,60}

Additional therapies for MC have been proposed, such as imatinib, thalidomide, bortezomib, and interleukin-2, but future controlled studies are necessary to assess their effectiveness and tolerability in this disease.^{43,61,62}

Primary angiitis of the central nervous system

■ JAMAL A. MIKDASHI

- Primary angiitis of the central nervous system is a rare syndrome characterized by inflammatory cell infiltration and necrosis of small and medium-sized blood vessel walls of the brain parenchyma, spinal cord, and leptomeninges.
- Headache, seizure, and cognitive impairment are the predominant symptoms, although various multifocal or diffuse neurologic symptoms with a remitting or progressive course may be present, including ischemic stroke and hemorrhage.
- The diagnosis is confirmed by either brain biopsy or cerebral angiography. Angiographic changes indicating an irregular course of vessels with characteristic segmental narrowing can be observed, but angiographic findings are normal at times and may not predict the pathologic findings. Cerebrospinal fluid and magnetic resonance imaging findings support the diagnosis of primary angiitis of the central nervous system.

HISTORY

Cerebral vasculitis was first reported in 1922 by Harbitz as an unusual type of arteritis associated with multinucleated giant cell arteritis of the small meninges and cerebrum.¹ Other documented cases of cerebral vasculitis described as noninfectious granulomatous angiitis with a predilection for the nervous system were reported by Newman and Wolf in 1952² and later by Cravioto and Fegin in 1959.³ Hughes and Brownell in 1966 described a progressive fatal form of vasculitis that is limited to the central nervous system (CNS) and was named primary angiitis of the CNS (PACNS) of unknown etiology.⁴

CASE DEFINITION AND CRITERIA

Problems with nomenclature and case definitions (isolated, primary, granulomatous angiitis) have evolved since the early description of cerebral vasculitis. It was difficult to separate polyarteritis and syphilitic endarteritis because of the occasional presence of similar pathologic findings of vascular necrosis, giant cells, and epithelioid cells in these disorders. Granulomatous formations may also occur in association with varicella-zoster virus infection, lymphoma, sarcoidosis, giant cell arteritis, amyloid angiopathy, and human immunodeficiency virus (HIV) infection. In addition, the heterogeneity of their clinical features and the lack of accurate and sensitive diagnostic tests have made categorization of these disorders uncertain.

No valid classification criteria have been established for the diagnosis of PACNS. Recommended criteria for the diagnosis of PACNS include the following⁵⁻⁷:

1. Clinical pattern of headaches and multifocal neurologic deficits that may remit or be present for at least 6 months unless the deficits are severe at onset or rapidly progressive
2. Cerebral angiography demonstrating segmental arterial narrowing and vessel occlusion affecting many cerebral vessels in the absence of proximal vessel atherosclerosis
3. Exclusion of systemic inflammation, vasculitis, and infection
4. Leptomeningeal/parenchymal biopsy specimen demonstrating vascular inflammation and exclusion of alternative diagnoses

PACNS is recognized as an inflammatory granulomatous disorder of small and medium-sized blood vessels of the arterial and venous system (angiitis) of the brain or spinal cord; it does not involve blood vessels or organs beyond the CNS. PACNS remains a diagnostic challenge. The clinical syndrome is rare, with poorly defined risk factors and varied clinical symptoms that may be identical to those produced by infection, occlusive vascular disease, and malignancy. Cerebral and leptomeningeal biopsy is the "gold standard" for the diagnosis of PACNS. Cerebrospinal fluid (CSF) and brain magnetic resonance imaging (MRI) findings support the diagnosis of PACNS, but neither laboratory tests nor neuroimaging allows a definite diagnosis to be made.

A definite diagnosis of PACNS is based on confirmed pathologic findings, whereas a probable diagnosis of PACNS is based on abnormal brain MRI and angiographic features of vasculitis with abnormal CSF studies in the absence of tissue confirmation. Atypical or possible PACNS refers to patients with a high probability of angiographic findings of vasculitis and normal CSF studies in the absence of a clear suspicion for reversible cerebral vasoconstriction syndrome (RCVS). Even though this categorization is based on tissue diagnosis, neuroimaging, angiographic findings, and CSF studies, it may not reflect differences in the validity of the diagnosis or response to treatment, and large multicenter prospective studies are necessary to establish these observations.

CLINICAL SYNDROMES OF CEREBRAL VASCULITIS

When vasculitis is clinically and pathologically restricted to the CNS, it is referred to as primary CNS vasculitis or PACNS and as secondary when associated with various other disorders (Box 164.1). The CNS may be involved as a single organ in systemic vasculitis, usually Behçet disease, polyarteritis nodosa (PAN), granulomatosis with polyangiitis (Wegener granulomatosis), systemic lupus erythematosus (SLE) and other connective tissue diseases, HIV infection, cutaneous herpes zoster infection, illicit drug use, lymphoma, amyloid angiopathy, and graft-versus-host disease.

PRIMARY CENTRAL NERVOUS SYSTEM VASCULITIS**Clinical findings**

The epidemiology of PACNS is poorly understood; it occurs predominantly in men in the fourth and fifth decades but may involve patients of all ages ranging from children to the elderly. PACNS in children is not addressed in this chapter. In the Mayo Clinic experience, the incidence of primary CNS vasculitis in Olmstead County, Minnesota, was estimated to be 2.4 cases per 1,000,000 person-years, with reduced long-term survival being associated with cerebral infarction and large-vessel involvement.⁸

Most case reports and clinical series of PACNS have described the findings to be insidious and slowly progressive, cumulative, and associated with multifocal neurologic dysfunction.^{9,10} At times the mode of onset is acute or subacute.

The typical manifestation consists of nonfocal symptoms such as headache and intermittent confusion and focal neurologic symptoms such as hemiparesis. Ataxia of limbs or gait, focal cortical dysfunction, including aphasia, and seizures are less frequent. Virtually every neurologic symptom has been reported at least once. Nonspecific visual complaints occur in approximately 15% of patients, but disorders of specific ocular motor nerves

or the optic nerve and visual field defects are much less common. Systemic symptoms such as fever or weight loss are generally absent.

Stroke occurs in approximately 15% of patients at one point during the illness and is mainly due to intracerebral hemorrhage.⁹ The disease rarely causes ischemic strokes or transient ischemic attacks in the absence of widespread inflammation, as verified by CSF studies (pleocytosis). Occasionally, patients may have multiple sclerosis–like symptoms involving the spinal cord or cerebellum with early relapses and partial remissions.¹¹ CNS vasculitis may develop in patients with rapidly progressive multiple sclerosis¹² or in those treated with biologic therapy for active relapsing multiple sclerosis.¹³

Spinal cord involvement is uncommon in PACNS.¹⁴ It may occur before cerebral symptoms, coincide with cortical involvement, or be manifested as an isolated neurologic syndrome of inflammatory myelopathy. Progressive paraparesis, acute transverse myelitis, and subdural hemorrhage secondary to multiple microaneurysms have been recorded. In most cases reported, PACNS is diagnosed after death and is associated with granulomatous histopathology. MRI of the spinal cord may reveal enhanced lesions over the

thoracic and lumbar vertebrae and the conus medullaris. Spinal cord involvement with PACNS features has also been reported in patients with Hodgkin disease, Behçet syndrome, SLE, and sarcoidosis. Thorough evaluation of the spinal cord is recommended in all patients with PACNS.

A tumorlike mass lesion has been recognized in PACNS.¹⁵ Clinical features include headache, focal and nonfocal neurologic syndromes, and seizures. The mass lesions are identified on brain MRI, and most patients have abnormal findings on CSF studies. Cerebral angiography shows a mass effect and not cerebral vasculitis. Excision biopsy is required for the diagnosis. The histopathologic findings of the mass lesion are described as being those of granulomas, granulomatous angiitis, lymphocytic angiitis, and amyloid-related angiitis. Even though excision of the mass lesion may be curative, aggressive immunosuppressive therapy is associated with a favorable outcome.

Pathogenesis

Despite advances in cellular and molecular immunology and genetics and improved understanding of the cerebral blood vessel damage, the pathogenic mechanism of PACNS remains unknown. There is little support for an immune complex process. The nature of the inflammatory infiltrate is not well studied. Immunophenotype testing has indicated the presence of memory/inducer CD45RO+ T cells, CD20+ B cells, and CD8+ T cells.¹⁶⁻¹⁸

The rarity of PACNS and the limited brain tissue obtained from patients have delayed progress in this complex syndrome. Understanding the role of triggering factors such as infections, in particular, *Mycoplasma gallisepticum*, varicella-zoster virus, West Nile virus, and HIV, may help in identifying specific clues to factors that mediate the neurovascular inflammation in PACNS. Elucidation of the role of amyloid deposition as a trigger of cerebral vascular inflammation might identify the link between primary CNS vasculitis and cerebral amyloid angiopathy.

Pathology

The characteristic pathologic findings include multiple small foci of infarction and hemorrhage, segmental necrotizing granulomatous inflammation of small and medium-sized leptomeningeal and cortical arteries, and Langhans or foreign body giant cells.^{7,19} A mixture of epithelioid cells, plasma cells, macrophages, scattered granulomas, and giant cells is often present (Fig. 164.1). Fibrinoid necrosis and eosinophilic infiltration may occur. Acute lesions frequently coexist with healing or healed lesions. Though present in most autopsy cases, giant cells are not required to make a diagnosis of PACNS.

The histopathology of PACNS is quite variable, and different patterns are recognized, including granulomatous, lymphocytic, and necrotizing vasculitis. Granulomatous vasculitis, a common pattern, is characterized by vasocentric destructive mononuclear inflammation associated with well-formed granulomas, multinucleated giant cells, or both. Amyloid deposition is frequent.

Lymphocytic vasculitis is characterized by lymphocytes with occasional plasma cells, typically in multiple layers, extending through the vascular wall, and causing vascular distortion or destruction. The presence of lymphocytic infiltrates is reported in children with PACNS and those with cocaine-associated CNS vasculitis. Lymphocytic infiltrates within blood vessel walls can be found in the context of various CNS pathology, including infections and malignancy.

Necrotizing vasculitis is less frequent and characterized by transmural fibrinoid necrosis similar to that seen in PAN. Necrotizing vasculitis involves predominantly small muscular arteries and is associated with disruption of

Fig. 164.1 Brain biopsy findings of granulomatous vasculitis include a mixture of epithelioid cells, plasma cells, macrophages, and scattered granulomas (hematoxylin-eosin staining).

the internal elastic lamina. Intracerebral and subarachnoid hemorrhage is common.

PACNS involves medium-sized arteries and small vessels, including arterioles, capillaries, veins, and venules. The inflamed vessels may become narrowed, occluded, and thrombosed and are associated with tissue ischemia and necrosis in the territories of the involved vessels (Fig. 164.2). The presence of aneurysms should raise suspicion for a mycotic inflammatory reaction, and an infectious etiology needs to be identified.

Laboratory investigations

No laboratory data are specific for PACNS. General medical laboratory data are unremarkable, including acute-phase reactants such as the erythrocyte sedimentation rate and C-reactive protein. Inflammatory markers of systemic vasculitis such as antineutrophil cytoplasmic antibodies may be encountered and indicate systemic vasculitis with CNS disease. Examination of CSF is essential given that it is abnormal in most documented autopsy cases of PACNS.⁷ The characteristic CSF findings in PACNS, though nonspecific, are those of aseptic and chronic meningitis with mild lymphocytic pleocytosis and mild to moderate protein elevation. Eosinophilic pleocytosis is rarely seen. The presence of oligoclonal bands with an elevated immunoglobulin G index is reported. The major role of CSF examination is to exclude infections and malignancy. Abnormal CSF findings are an indication for angiography.

Brain imaging

No computed tomography (CT) findings are typical of PACNS. CT is less sensitive than MRI in evaluating the changes caused by cerebral vasculitis except for cerebral hemorrhage. CT angiography or multislice CT is useful for the evaluation of large-vessel vasculitis. MRI is the most sensitive technique in detecting changes in cerebral vasculitis involving large, medium,

and small vessels, but it lacks specificity in histopathologically confirmed cases. Brain MRI almost always has abnormal findings in PACNS. Serial brain MRI may be required to increase its sensitivity. Digital subtraction angiography should be considered when findings on brain MRI are normal and clinical suspicion for cerebral vasculitis remains high. Areas of stenosis, dilatation, and occlusion in medium and small arteries are suggestive of cerebral vasculitis.

The most common findings of vasculitis on brain MRI are focal areas of high signal intensity. Multiple and often bilateral infarcts of various age in more than one vascular territory are suggestive of vasculitis. Mural thickening, hemorrhages, leukoencephalopathy, and gadolinium-enhanced lesions in the cortex, deep white matter, or leptomeninges can also be demonstrated.²⁰ A single tumorlike lesion or isolated myelopathies are also described.

High-resolution contrast-enhanced MRI of the vessel wall may help in differentiating reversible cerebral vasoconstriction disorders from cerebral vasculitis. Fat-suppressed T1-weighted images are sensitive for vessel wall enhancement.²¹ Vessel wall thickening and intramural enhancement, particularly of the large arteries, are specific for CNS vasculitis.

Magnetic resonance angiography (MRA) provides complementary findings to conventional brain MRI. MRA is the principal modality for investigating patients thought to have intracranial stenosis, but only in large to medium-sized brain arteries that can be imaged with a high diagnostic accuracy, and it is generally of little use in small-vessel PACNS. High field strength (7 T) offers the possibility of directly evaluating small vessels. The changes induced by vasculitis seen on MRA are similar to those seen on conventional angiography and include stenosis with occlusion (Fig. 164.3). MRA may overestimate the severity of stenosis at points of vessel branching or vascular occlusion.

Advanced MR techniques, including MR perfusion scans, can demonstrate the microscopic flow of blood through tissue. They provide measures of cerebral blood flow, cerebral blood volume, and the mean transit time of

Fig. 164.2 (a) Brain stem destruction secondary to cerebral vasculitis with swelling and opacification of the meninges. (b) Cerebral vasculitis with bilateral parasagittal hemorrhagic lesions and left subfalcine herniation.

Fig. 164.3 Magnetic resonance imaging (a) and computed tomographic angiography (b) of cerebral artery branches with focal arterial narrowing (arrows) in cerebral vasculitis. The inflamed vessels may become narrowed, occluded, and thrombosed and are associated with tissue ischemia and necrosis in the territories of the involved vessels.

a unit of blood through a unit of tissue. Cerebral vasculitis is characterized by a decrease in cerebral blood volume consistent with hypoperfusion. These methods are well suited to measure treatment efficacy with serial examinations.

Diffusion weighted imaging (DWI) measures diffusion of water through the brain. The apparent diffusion coefficient (ADC) can be used to measure the integrity of structures in the brain. Although the restriction of diffusion seen with acute infarction is a marker of loss of tissue integrity, an increase in the ADC has been reported in cerebral vasculitis with normal findings on conventional brain MRI. DWI may allow earlier detection of breakdown of structures and may help in prognosis and monitoring of treated patients.

Magnetic resonance spectroscopy can be used to measure in vivo metabolism. Several studies have shown a decrease in *N*-acetylaspartate in vasculitis, a marker of neuronal and cell wall integrity. Fluorodeoxyglucose-labeled positron emission tomography (FDG PET) can detect glucose utilization and demonstrate areas of hypometabolism and hypermetabolism. Although FDG PET can visualize inflammatory changes in vessels larger than 4 mm, its use is limited, however, to large vessels. What is more important is that the abnormal diffuse and focal perfusion patterns seen on FDG PET or single-photon emission computed tomography do not always correlate with neurologic symptoms or distinguish vasculitis from nonvasculitic vasculopathy.

Currently, cerebral angiography with its anatomic and hemodynamic data and three-dimensional capability of demonstrating bilateral large- or small-vessel changes consistent with angiitis is frequently used as the basis for establishing the diagnosis of PACNS. The “typical” findings of cerebral vasculitis on four-vessel catheter angiography are widespread segmental changes in the large, intermediate, and small arteries of several territories of the cerebral circulation, microaneurysmal dilatation, vessel irregularities, and multiple occlusions with sharp cutoffs (Fig. 164.4). Occlusion of large cerebral vessels is rare. Small aneurysms, usually on vessels more distal than those bearing congenital saccular aneurysms, are occasionally present but cannot be distinguished from aneurysms complicating atrial myxoma or infective endocarditis.

The “typical” angiographic features of cerebral vasculitis have low sensitivity and specificity. Such features are found in approximately a third of patients with histopathologically confirmed PACNS and may be seen in those with CNS infection, atherosclerosis, cerebral embolism, and vasospasm of diverse causes.²² In addition, the changes induced by cerebral vasculitis are less apparent in large vessels during early phases of the illness. Small-vessel vasculitis is not detected in vessels smaller than 0.2 mm because they are below the resolution of cerebral angiography. Thus, many patients with histopathologically documented PACNS have entirely normal angiographic or nonspecific vascular findings.²³

Biopsy findings

Brain, spinal cord, and leptomeningeal biopsy remains the gold standard for the diagnosis of PACNS. The procedure of choice is open-wedged biopsy of the tip of the nondominant temporal or frontal lobe with excision of 1 cm³ of the overlying leptomeninges and gray and white matter of the underlying cortex. Directing the biopsy to an area of leptomeningeal enhancement or a focal or mass lesion when present may increase the diagnostic yield. False-negative biopsy findings occur in up to 25% of autopsy cases because of focal lesions and sampling errors.²⁴

The role of biopsy is not only to provide proof of the diagnosis of PACNS but also to exclude alternative diagnoses, including infection and malignancy. Findings on brain or leptomeningeal biopsy suggestive of nonspecific gliosis, perivascular inflammation, and parenchymal ischemic damage should be interpreted with caution and correlated with the clinical context and imaging studies. Although tissue biopsy is the most reliable approach, the presence of vasculitis in the biopsy specimen may reflect a primary infectious process with secondary vascular inflammation. A negative biopsy tissue culture remains a crucial element for the diagnosis of PACNS.

Differential diagnosis

Certain disorders that are not vasculitis in origin but that mimic PACNS and pose a challenge to the diagnosis of PACNS are listed in Box 164.2. A substantial number of patients will be found to have the clinical syndrome of PACNS but may have cerebral vasospasm with no clear evidence of cerebral vasculitis.

Reversible Cerebral Vasoconstriction Syndromes

RCVSs comprise a group of disorders characterized by multifocal reversible segmental vasoconstriction of the cerebral vessels and lack of vasculitic

Fig. 164.4 Oblique lateral four-vessel angiography of cerebral vasculitis. Characteristic focal cerebral arterial narrowing (arrows) with segmental changes, occlusions, and a sharp cutoff are seen in several territories.

BOX 164.2 NONINFLAMMATORY VASCULOPATHIC DISORDERS THAT MIMIC PRIMARY ANGIITIS OF THE CENTRAL NERVOUS SYSTEM

- Reversible cerebral vasoconstriction syndromes
- Intracranial atherosclerosis
- Cerebral embolism
- Hypercoagulable state
- Intracranial vertebral artery dissection
- Neurofibromatosis
- Fibromuscular dysplasia
- Susac syndrome
- Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy
- Moyamoya disease
- Acute multifocal placoid pigment epitheliopathy
- Mitochondrial encephalopathy, lactic acidosis, and strokelike illness (MELAS)
- Progressive multifocal leukoencephalopathy
- Reversible posterior leukoencephalopathy syndrome
- Demyelinating syndrome

changes on brain biopsy.²⁵ RCVSs include Call-Fleming syndrome; thunderclap headache; postpartum angiopathy; migraine cerebral vasospasm; benign angiopathy of the CNS; exposure to vasoactive substances, including adrenergic or serotonergic drugs; and less commonly, severe hypertension, pheochromocytoma, metabolic disorders, brain tumors, and brain surgery. In very rare instances, vasculitis has been reported with amphetamine and cocaine use.^{26,27}

RCVS has a female preponderance with a mean age at onset of around 45 years. A provocative factor can be identified in 12% to 60% of patients. The pathogenic mechanism of RCVS is largely unknown and is supposedly due to a transient alteration in cerebrovascular tone.

The clinical course of RCVS is uniphasic and may vary from pure cephalgia to rare catastrophic events associated with several hemorrhagic and ischemic strokes, brain edema, and death. The initial feature is acute severe “thunderclap” headaches, which may be recurrent over a 1- to 3-week period, followed at times by focal neurologic symptoms and seizures. Major clinical complications include localized cortical subarachnoid hemorrhage, watershed infarcts, and posterior reversible leukoencephalopathy. Ischemic

stroke with transient ischemic strokes and cerebral infarcts or microscopic hemorrhage occurs a few days after the initial normal findings on neuroimaging, and cerebral vasoconstriction may arise 2 to 3 weeks after clinical onset.

The diagnosis of RCVS should be suspected (Table 164.1) in a patient with an acute onset of symptoms in a specific clinical setting, such as in the postpartum period, in the context of migraine headache, or following the ingestion of a drug that causes cerebral vasospasm. CSF examination shows normal to mild involvement. No specific brain MRI findings accompany RCVS; high-resolution contrast-enhanced MRI of the vessel wall may enable differentiation between RCVS and CNS vasculitis. The key diagnostic element is reversibility of the angiographic changes within 12 weeks after onset, which is typical of RCVS. When cerebral vasculitis resolves spontaneously or with a short course of glucocorticoid therapy, a form of RCVS should be suspected. Nimodipine seems to reduce thunderclap headaches with 48 hours but has no definite effect on the outcome of hemorrhagic or ischemic stroke. Relapses are rare.

TABLE 164.1
Demographic characteristics, clinical features, and imaging studies distinguishing PACNS from RCVS

Feature	PACNS	RCVS
Demographics		
Age at onset (yr)	40-50	20-40
Gender predilection	Men	Women
Clinical features	Variable	Cephalgia Catastrophic stroke/edema
Onset of symptoms	Insidious	Acute/subacute
Provocative factors	None	Vasoactive medication Eclampsia/postpartum status Migraine
Headache	Progressive	Thunderclap
Stroke, onset	During the course of illness	Early, a few days after initial normal imaging
Course	Progressive	Uniphasic Rapid dynamic nature
Diagnosis		
CSF	Abnormal	Normal
High-resolution MRI of the vessel wall	Arterial wall enhancement	Lack of contrast enhancement
Treatment	Glucocorticoids/ immunosuppressives	Calcium channel blockers/ nimodipine Magnesium
Resolution at follow-up angiography	Months	Within 3 mo

CSF, cerebrospinal fluid; MRI, magnetic resonance imaging; PACNS, primary angiitis of the central nervous system; RCVS, reversible cerebral vasoconstriction syndrome.

Amyloid angiitis

Cerebral amyloid angiopathy (CAA) is a nonvasculitic inflammatory disorder that is defined by the accumulation of amyloid in the walls of small and medium-sized cerebral arteries; it is often recognized by spontaneous and recurrent hemorrhages in the brain, spinal cord, and leptomeninges. Intracerebral lobar hemorrhage is sometimes silent, and patients may have progressive dementia and spastic paraparesis. Recently, a few case reports have described granulomatous angiitis in patients with sporadic, amyloid beta peptide (A β)-related CAA.²⁸

Inflammatory amyloid angiopathy is associated with subacute cognitive decline, headaches, seizures, focal neurologic deficits, and hallucinations. Most patients are found to have white matter hyperintensities and microhemorrhages on imaging studies that are of similar appearance to those in PACNS. CSF examination usually shows modest elevation of protein and lymphocytic pleocytosis; rarely, eosinophilic pleocytosis is reported. The histopathology of brain lesions includes vasculitic features with angiodestructive inflammation that is often granulomatous and associated with meningeal lymphocytosis (Fig. 164.5). A β is consistently present in abundance in affected blood vessels but is usually scanty within the parenchyma of the cerebral cortex.

Paraneoplastic angiitis

Hodgkin disease, non-Hodgkin lymphoma, and intravascular lymphomatous and angio-immunolymphoproliferative diseases may be accompanied by paraneoplastic angiitis manifested as granulomatous angiitis of the CNS or recurrent cerebral venous thrombosis,²⁹ and such conditions have a poor outcome. CNS lymphomas may have imaging studies that are characteristic of vasculitis of the CNS and spinal cord and, histologically, may be indistinguishable from vasculitis. Necrotizing arteritis and microvasculitis have also been described in patients with breast cancer and occult small cell lung cancer with related anti-Hu-associated paraneoplastic encephalomyelitis and sensory neuropathy. Molecular genetic testing and immunohistochemical staining are indispensable diagnostic tools for verification.

Diagnostic approach

The major consideration in the approach to a patient with possible PACNS is to decide whether the clinical manifestations are restricted to the nervous system or whether they are part of a more active systemic disease. A careful history and physical examination of the skin, eyes, paranasal sinuses, testicles, kidneys, and lungs is critical in the process of the differential diagnosis of PACNS.

Correct diagnosis of PACNS requires a high index of suspicion coupled with knowledge of disorders that may masquerade as PACNS. An algorithmic approach with a flow sheet containing questions has been used when encountering a patient with a possible diagnosis of PACNS (Box 164.3), but a definite diagnosis is made only after extensive investigation.^{30,31}

PACNS should be suspected in the setting of chronic meningitis; recurrent focal neurologic symptoms such as atypical strokes; unexplained diffuse neurologic symptoms such as headache, seizure, and cognitive abnormalities; or spinal cord dysfunction not associated with systemic disease or any other process.

General laboratory and serologic evaluation is helpful in the differential diagnosis of PACNS (Box 164.4). CSF studies are crucial for eliminating infections, malignancy, or alternative process. In such circumstances,

Fig. 164.5 (a) Cerebral vasculitis with amorphous eosinophilic deposits in the blood vessel wall (A β amyloid angiitis). (b) Angiodestructive inflammation with granuloma formation and meningeal lymphocytosis.

BOX 164.3 ALGORITHMIC APPROACH TO THE DIAGNOSIS OF PACNS

1. *Is there a known systemic disease?*
 - a. Systemic vasculitis, connective tissue diseases
 - b. Infection: HIV, viral, bacterial, Lyme, syphilis, mycobacterial, fungal, protozoal
 - c. Malignant hypertension, eclampsia, infective endocarditis, atrial myxoma/thrombus, patent foramen ovale, disrupted carotid plaque
 - d. Neoplasm: intravascular lymphoma, lymphoid granulomatosis
 - e. Drug exposure and illicit drug use
 - f. Recent trauma, neurosurgery, intracranial dissection
2. *Are there abnormal findings on MRI (brain, leptomeninges)?*
 - a. Vasculitis, vascular disorders including stroke syndrome or arterial venous malformation, demyelinating syndrome, sarcoidosis, infection, neoplasm
3. *Is there abnormal cerebrospinal fluid (pleocytosis)?*
 - a. Acute, recurrent, and chronic meningitis; partially treated bacterial (pyogenic), HIV, viral, syphilitic, Lyme, mycobacterial, fungal, protozoal infection
 - b. Noninfectious: PML, sarcoidosis, Behçet disease, neoplasm
4. *Are there abnormal findings on conventional cerebral angiography?*
 - a. True vasculitis: PACNS, systemic vasculitis
 - b. Infection
 - c. Reversible cerebral vasoconstriction syndromes
 - d. Neoplasm
 - e. Subarachnoid hemorrhage
 - f. Trauma
5. *Are there abnormal biopsy findings with inflammation?*
 - a. True vasculitis: PACNS, secondary vasculitis
 - b. Perivascular inflammation: demyelinating syndrome, undersampled vasculitis, infection (PML, SSPE, VZV), lymphoma
 - c. Neoplasm: lymphoma, metastatic malignancy

Small-vessel PACNS may have normal findings on cerebral angiography. However, PACNS is unlikely in the context of normal findings on brain MRI and normal spinal fluid studies. HIV, human immunodeficiency virus; MRI, brain magnetic resonance imaging; PACNS, primary angiitis of the central nervous system; PML, progressive multifocal leukoencephalopathy; SSPE, subacute sclerosing panencephalitis; VZV, varicella-zoster virus.

absence of CSF abnormalities and normal findings on MRI of the brain are associated with a high negative predictive value for the development of PACNS, which may obviate the need to perform cerebral angiography or blind brain biopsy. This assumption is based on the observation of different case series in which the majority of patients with PACNS had abnormal CSF findings and from patients with PACNS confirmed by histopathology who continue to have never completely normal CSF studies on repeated examination.^{32,33}

Even though neuroimaging plays a crucial role in the differential diagnosis of PACNS, such studies remain nonspecific or insufficient for the diagnosis of PACNS. With its good safety profile, cerebral angiography is generally required for confirmation of cerebral vasculitis before initiating immunosuppressive therapy and when brain MRI findings are suspicious for angiitis in conjunction with the clinical history. Repeated angiography is indicated before brain biopsy if the angiographic findings are suggestive of RCVS.

Brain biopsy is recommended when patients have chronic meningitis and an infectious process or malignancy is suspected. Brain biopsy is necessary when a focal inflammatory lesion or mass effect is seen on neuroimaging studies. Confirmation of the diagnosis by brain biopsy is crucial before the use of aggressive immunosuppressive therapy.

Treatment

No evidence-based treatment recommendations are available for primary CNS vasculitis. Initial reports described the clinical course of PACNS as being progressive, associated with serious morbidity, and in most cases, fatal. Treatment with glucocorticoids and cyclophosphamide achieves remission and disease control in many patients; however, some patients respond to prednisone alone. Given the aggressive course based on historical cases in the literature, the currently recommended therapy should follow the general treatment of systemic vasculitis.³⁴

In documented cases of PACNS, a combination of oral glucocorticoids and oral cyclophosphamide is suggested for at least 6 months. Intravenous methylprednisolone and cyclophosphamide should be initiated in patients with a rapidly progressive course, large-vessel involvement, and recurrent cerebral infarctions. This group of patients is known to have a poor response to treatment and may have a fatal outcome.

BOX 164.4 LABORATORY EVALUATION FOR SUSPECTED PACNS**General studies**

Complete blood count
Complete metabolic panel and hepatic function test
Erythrocyte sedimentation rate
C-reactive protein
Lipid panel
Urinalysis and urine microalbumin
Urine toxicology screen
Prothrombin and thromboplastin time
Proteins S and C
Serum and urine protein electrophoresis and serum immunoglobulin electrophoresis
Quantitative immunoglobulin
Acute hepatitis panel, B and C virus
HIV

Serology panel

Rheumatoid factor
Antinuclear antibody
Antibodies to Ro/SSA, La/SSB, Sm, and RNP antigens
Anticardiolipin antibody and lupus anticoagulant
Serum complement level: C2, C3, C4, and CH₅₀
Antibody to double-stranded DNA
Antineutrophil cytoplasmic antibody
Angiotensin-converting enzyme
Lyme titer (ELISA and Western blot)
Serum cryoglobulins
Treponema pallidum, rapid plasma antigen, and fluorescent treponemal antigen

Cerebrospinal fluid studies

Protein
Glucose
Cell count
IgG level and index
Oligoclonal bands
Venereal Disease Research Laboratory (VDRL)
Viral antibodies and antigens and polymerase chain reaction for West Nile virus, cytomegalovirus, herpes simplex and herpes zoster, and HIV
Lyme titer
ANCA titer
ACE level
India ink, Gram stain, and routine cultures, including acid-fast bacillus stain

ACE, angiotensin-converting enzyme; ANCA, antineutrophil cytoplasmic antibody; CH₅₀, 50% hemolyzing dose of complement; ELISA, enzyme-linked immunosorbent assay; HIV, human immunodeficiency virus; PACNS, primary angiitis of the central nervous system; RNP, ribonucleoprotein.

The initial dose of prednisone recommended to achieve disease control is 1 mg/kg/day. Intravenous methylprednisolone at 15 mg/kg/day for 3 to 5 days may be used, and daily prednisone is then initiated. Cyclophosphamide induction therapy is recommended, either oral daily intake at a starting dose of 1.5 to 2.0 mg/kg/day or intermittent monthly intravenous doses of 600 to 750 mg/m² for a 6-month period. Strict patient-specific monitoring of treatment-related toxicity and infection remains essential. Thus, the cyclophosphamide dose should be adjusted to the serum creatinine level to avoid severe leukopenia. The white blood cell count should be kept above 3500/μL.

In the event of clinical remission, treatment should be switched to anti-metabolite therapy, such as azathioprine or mycophenolate mofetil, for the duration of therapy. Methotrexate may be used, but its efficacy in treating CNS disease is limited by poor penetration through the blood-brain barrier. Similarly, oral glucocorticoids should be tapered to a smaller daily dose at 4 to 6 weeks after initiation of treatment.

No optimal treatment duration has been recommended, and management of relapse is not well studied. The role of antiplatelet therapy, vasodilators, calcium channel blockers, plasma exchange, intravenous immunoglobulin therapy, or other immunomodulatory therapy, including anti-tumor necrosis factor-α therapy or rituximab, awaits prospective multicenter clinical studies in patients with biopsy-proven PACNS.

No clinical response endpoints have been established for PACNS. Frequent neurologic evaluation for clinical response is recommended on a monthly basis during the early course of treatment. Clinically meaningful improvement may be suggested by improved headache and mental status,

Fig. 164.6 Brain magnetic resonance images (a and b) and cerebral angiograms (c and d) of cerebral vasculitis before (a and c) and after (b and d) immunosuppressive treatment. (a) Brain magnetic resonance imaging with stable multiple remote prior lacunar infarcts (arrows) with no new diffusion weighted or enhancing lesion. (c) Cerebral angiography shows mild improvement (arrows) in the areas of vascular abnormality involving cortical vessels from all intracranial circulatory territories. A 2-mm sidewall left cavernous internal carotid artery aneurysm and a 2-mm right posterior communicating artery aneurysm were unchanged.

a fall in acute-phase response, lack of new lesions on repeated MRI, or resolution of previous inflammatory lesions (Fig. 164.6).

CSF abnormalities serve as a useful indicator of decreased disease activity and should be evaluated after 12 weeks of therapy. Disease activity and damage can also be monitored with serial brain MRI or MRA every 3 months during the first year and every 6 months during the second year to assess for resolution of infarcts, as well as to detect silent new ischemic lesions during the tapering period of immunosuppressive treatment. Repeated cerebral angiography may be indicated if the diagnosis is not clear, response to treatment is poor, a relapse of symptoms occurs, or a suspicious scar tissue lesion or mass lesion is found on MRI.³⁵

Routine vaccination against influenza and pneumonia is suggested, in addition to antimicrobial prophylaxis with trimethoprim-sulfamethoxazole to prevent *Pneumocystis jiroveci* pneumonia. Close monitoring of treatment-related adverse events, including infection, osteoporosis, and other complications such as epileptic seizures, depression, cognitive dysfunction, cardiac arrhythmias, thrombosis, and respiratory and urinary tract infections is essential; early diagnosis and adequate treatment are required to prevent serious morbidity and mortality. Efforts to limit accelerated atherosclerosis through aggressive control of diabetes mellitus, hypertension, and dyslipidemia, as well as smoking cessation, are emphasized.

OTHER SYSTEMIC ILLNESSES

165

Monogenic autoinflammatory diseases

■ RAPHAELA GOLDBACH-MANSKY ■ ADRIANA ALMEIDA DE JESUS ■ MICHAEL F. McDERMOTT
■ DANIEL L. KASTNER

- Monogenic autoinflammatory diseases are a group of illnesses that typically manifest in childhood and are caused by single-gene defects in innate immune regulatory pathways. These illnesses can mimic infections clinically, but the inflammatory lesions are aseptic.
- The prototypic autoinflammatory diseases are characterized by episodes of fever flares associated with localized inflammation, with periods of remission. Another group of autoinflammatory syndromes is caused by single-gene mutations in loci regulating interleukin-1 (IL-1) processing, secretion, and signaling.
- A number of rare autoinflammatory diseases of Mendelian inheritance show variable responses to IL-1 inhibition and an inflammatory phenotype that is not well understood.
- Recently, novel autoinflammatory conditions unresponsive to IL-1-blocking therapy have been identified; these include the proteasome-associated autoinflammatory syndromes as well as early-onset inflammatory bowel disease caused by mutations in the IL-10 signaling pathway.
- Systemic AA amyloidosis can occur in any of these illnesses.
- Early diagnosis of these syndromes is important because effective therapies are available.

INTRODUCTION

The era of monogenic autoinflammatory diseases started in 1997 with the discovery that autosomal recessive mutations in the then-novel gene *MEFV* cause the periodic fever syndrome known as *familial Mediterranean fever*^{1,2} and the subsequent description of autosomal dominant mutations in *TNFRSF1A*, encoding the 55-kDa tumor necrosis factor (TNF) receptor, as the cause of another periodic fever syndrome, now termed *TNF receptor-associated periodic syndrome*, in 1999.³ The term *autoinflammatory diseases* was proposed because the genetics suggested that these periodic fever syndromes are caused by dysregulation of innate immune pathways.

Demographic, genetic, and clinical features of the Mendelian autoinflammatory diseases described in this chapter are summarized in Table 165.1a and b. In many instances, a clinical diagnosis can be made on the basis of clinical features, and the diagnosis is then confirmed by genetic testing.

THE “CLASSIC” PERIODIC FEVER SYNDROMES

Familial Mediterranean fever

Background

Familial Mediterranean fever (FMF) (OMIM #249100) is most prevalent in individuals of Ashkenazi Jewish, non-Ashkenazi Jewish, Armenian, Arab,

Turkish, and Italian ancestry. DNA analysis has also confirmed the presence of FMF in individuals with no known Mediterranean or Middle Eastern ancestry. In the past, two *MEFV* mutations were thought to be necessary for genetic diagnosis of FMF, consistent with an autosomal recessive mode of inheritance. However, there has been a growing realization that many patients with clinical FMF have only a single demonstrable *MEFV* mutation even with complete gene sequencing.^{4,5} DNA studies have raised the possibility that, at least for certain rare *MEFV* mutations, dominant inheritance is possible.^{6,7}

Approximately 90% of patients with FMF exhibit their first symptoms by the age of 20.^{8,9} Increasingly, however, genetic testing has allowed the recognition of mild disease in adults, who often give a history of symptoms dating back to childhood. There is an excess of male cases over female (usually with a male-female ratio of about 1.5:1 to 2.0:1), and despite the possibility of underdiagnosis, the incidence of clinically diagnosed FMF has been found to be as high as 1 in 248 individuals in the Libyan Jewish population,^{5,10} which implies a carrier frequency of at least 1 in 8 individuals, assuming a simple recessive model of inheritance. Environmental factors are increasingly implicated in disease severity, with milder phenotypes seen in Eastern Mediterranean patients with FMF who migrate to Europe.¹¹

Genetics and pathophysiology

The FMF gene *MEFV* was identified by positional cloning by two independent groups in 1997.^{1,2} It encodes a 781-amino-acid protein product that has been named *pyrin* and *marenostrin* by the two teams.^{1,2} Four missense mutations in exon 10, M680I (isoleucine for methionine at codon 680), M694V (valine for methionine at codon 694), M694I (isoleucine for methionine at codon 694), and V726A (alanine for valine at codon 726), were found in absolute association with disease in two large panels of families.^{1,2}

Pyrin is expressed in neutrophils, eosinophils, monocytes, dendritic cells, and synovial fibroblasts but not at significant levels in lymphocytes.^{12,13} Recognition of pyrin's N-terminal homotypic interaction domain, PYD, is the basis for two working hypotheses on pyrin function (Fig. 165.1a). Pyrin binds an adaptor protein called ASC (apoptosis-associated speck-like protein with a caspase recruitment domain)¹⁴ that consists of an N-terminal PYD and a C-terminal caspase activation and recruitment domain (CARD).¹⁵ The PYD of pyrin binds the PYD of ASC, whereas the CARD of ASC binds certain other CARD proteins, which regulate cytokine production, apoptosis, and nuclear factor- κ B (NF- κ B) activation. By one hypothesis, the pyrin-ASC interaction may inhibit the assembly of the inflammasome, a macromolecular complex that includes ASC and cryopyrin and is known to activate interleukin-1 (IL-1 β) and IL-18 (see Fig. 165.1a).¹⁶⁻¹⁸ Mice expressing a truncated pyrin are more sensitive to endotoxin, with increased caspase-1 activation, increased IL-1 β maturation, and a defect in macrophage apoptosis¹⁹; and macrophages from pyrin knockout mice produce increased amounts of IL-1 β when stimulated in culture. Moreover, pyrin has an additional inhibitory effect on IL-1 β production through its C-terminal B30.2 (SPRY) domain¹⁹ and, consistent with an antiinflammatory role for pyrin, the use of small interfering RNA to knock down pyrin in a human

Fig. 165.1 Activation of proinflammatory signaling pathways in cryopyrin-associated periodic syndromes (CAPS); familial Mediterranean fever (FMF); pediatric granulomatous arthritis (PGA); pyogenic arthritis, pyoderma gangrenosum, and acne (PAPA) syndrome; and tumor necrosis factor (TNF) receptor-associated periodic syndrome (TRAPS). (a) Mutated NALP3 (which causes CAPS) is constitutively activated and oligomerizes and binds to adapter molecules ASC and CARDINAL to form an active catalytic complex with two procaspase-1 molecules. Via autocatalysis, this complex generates active caspase-1, which cleaves inactive pro-interleukin-1β (pro-IL-1β) to its active form, interleukin-1β (IL-1β). Wild-type pyrin can inhibit inflammasome activation by direct binding to caspase-1. Mutated pyrin (which causes FMF) cannot exert its inhibitory effect on the inflammasome, which leads to unopposed inflammasome activation. Wild-type pyrin can also interact directly with ASC to form the "pyrin inflammasome," which is activated in the presence of FMF-causing mutations. Wild-type PSTPIP1, another regulatory molecule of the NALP3 inflammasome, binds to pyrin. Mutated PSTPIP1 (which causes PAPA syndrome) cannot dissociate from its binding to pyrin, which leads to uninhibited inflammasome and pyrin inflammasome activities. (b) Bacterial peptidoglycans stimulate the NOD2 (nucleotide-binding oligomerization domain 2) inflammasome. RIP2 is recruited, which leads to activation of nuclear factor-κB (NF-κB) and mitogen-activated protein kinase (MAPK) signaling pathways. Mutations in the NACHT domain (which cause PGA) lead to presumed autoactivation of NOD2 and constitutive activation of NF-κB and proinflammatory cytokines. (c) TNF receptor 1 (TNFR1) molecules are transported from endoplasmic reticulum (ER) to the Golgi complex and then to the cell surface. Wild-type TNFR1 complexes are bound to extracellular TNF, which leads to NF-κB activation. Receptor cleavage from the cell surface abrogates receptor signaling, and the soluble receptor can buffer soluble TNF. Mutated TNFR1 (which causes TRAPS) is misfolded and cannot be transported to the cell surface. Misfolded TNFR1 is sequestered in the ER and may further lead to decreased TNF-induced apoptotic signaling. TRAPS-associated TNFR1 mutations are associated with elevated baseline levels of reactive oxygen species (ROS), an enhanced oxidative capacity, and mitochondrial ROS generation. ASC, apoptosis-associated specklike protein with a caspase recruitment domain; CARD, caspase activation and recruitment domain; DAMPs, damage-associated molecular patterns; IFN-β, interferon-β; LRR, leucine-rich repeat; PAMPs, pathogen-associated molecular patterns; PYD, pyrin domain.

monocytic cell line increased IL-1β production *in vitro*.²⁰ Alternatively, pyrin and ASC may themselves form their own "inflammasome complex" with caspase-1 to activate IL-1β, as has been demonstrated *in vitro* (see Fig. 165.1b).¹⁹ A mouse model in which human pyrin mutations have been genetically introduced supports this latter view,¹⁵ as does the paucity of null mutations in FMF patients and the observation of biochemical inflammation in *MEFV* heterozygotes.²¹

Currently, over 100 FMF-associated *MEFV* mutations are listed in the Infevers online database of periodic fever mutations, although the total number of reported sequence variants exceeds 250.²² Almost half of the known mutations are in exon 10, encoding the B30.2 (SPRY) domain.

Exon 10 also includes two mutational "hot spots" (M680 and M694) that have more than one known mutation. A second major cluster of *MEFV* sequence variation is in exon 2. In contrast with the exon 10 mutations, these sequence variants, such as E148Q, are of uncertain significance and are less pathogenic mutations; they may simply be functional polymorphisms that alone are usually insufficient to cause FMF but may nonspecifically affect the overall severity of inflammation.²³ The majority of FMF-associated *MEFV* mutations represent missense single amino acid substitutions.

M694V homozygotes have an increased risk of amyloidosis,^{24,25} and some studies additionally associate this genotype with an earlier age of

onset, greater frequency of attacks, arthritis, and erysipelas-like erythema.^{24,25} M694I, M680I, and the V726A-E148Q complex allele may also confer a more severe phenotype.⁶ There is evidence that the deletion mutation at codon 694 and the M694I-E148Q complex allele as well as mutations at residue 577 are dominantly inherited.^{6,7} The E148Q substitution is usually found in FMF patients who are compound heterozygotes for E148Q and an exon 10 mutation, but it may also be seen as a complex allele in cis with an exon 10 mutation.^{26,27} Like the E148Q mutation, the P369S and R408Q substitutions, which are encoded in exon 3, are of uncertain significance.²⁸

Clinical features

The acute attacks of FMF are typically characterized by fever and serositis, synovitis, or skin rash. Attacks usually last for 24 to 72 hours, although arthritis can persist for up to 1 week. Attacks can occur weekly or as infrequently as once every few years. Physical exertion, emotional stress, and menses have been associated with attacks in some patients, but in many cases there is no obvious provocation. Some patients experience a prodromal sensation for several hours before the onset of the attack, and chills often herald the onset of fever.

Abdominal pain is the second most common manifestation of FMF and occurs in over 90% of patients. At its worst, the abdominal pain of FMF mimics an acute surgical abdomen, and many patients who seek treatment because of such pain early in their disease undergo one or more exploratory laparotomies, which usually reveal sterile peritonitis and sometimes unexplained adhesions, but no evidence of appendicitis. Pleural attacks are also common in FMF; pleurisy may be more frequent among Armenians than in other populations.⁹ Pleural attacks are usually unilateral, with sharp, stabbing chest pain on inspiration or coughing and sometimes with shoulder pain referred from the diaphragm.

Symptomatic non-uremic pericarditis is rare, even with tamponade.^{29,30} Small pericardial effusions with mild or no symptoms can sometimes be detected by echocardiography (Fig. 165.2a).

FMF arthritis often presents in childhood, most frequently manifesting as monoarticular arthritis affecting the knee or ankle, with symmetric

oligoarthritis being the next most common presentation.³¹ During the acute arthritic attacks of FMF, there may be large sterile synovial effusions with neutrophil counts of the magnitude seen in septic arthritis. Despite this, the natural history of the acute arthritis of FMF is complete resolution with no radiographic residua. In patients not treated with colchicine, chronic monoarticular arthritis can develop, and when located in the hip, this can eventually necessitate joint replacement.³² FMF patients may also be at increased risk of sacroiliitis, irrespective of HLA-B27 status or colchicine prophylaxis.³³

The most characteristic skin lesion of FMF is a tender erythematous plaque on the dorsum of the foot, ankle or lower leg, termed *erysipelas-like erythema* (see Fig. 165.2b). Histologic evaluation of biopsy specimens from skin lesions shows perivascular, primarily polymorphonuclear infiltrates³⁴; a larger, more recent study showed a more mixed cellular infiltrate³⁵ (see Fig. 165.2c), which likely indicates different stages of the rash at biopsy. Deposits of C3 can be demonstrated in vessel walls, but vasculitis is not observed.

Attacks of FMF can also manifest with exertional myalgia of the lower extremities, usually without fever, lasting from a few hours to 2 to 3 days. They occur in about 20% of patients; shorter-lasting, mild myalgia can sometimes occur without strenuous exercise.³¹ In a small percentage of patients, episodes of myalgia of the extremities can be prolonged (up to 6 weeks), severe, debilitating, and associated with fever, increased erythrocyte sedimentation rate (ESR), and a normal creatine kinase level.³⁶ This “protracted febrile myalgia” is thought to be due to vasculitis.³⁶ A small percentage of boys with FMF develop acute scrotal pain resulting from inflammation of the tunica vaginalis.³⁷ There have also been isolated reports of aseptic meningitis in FMF.³⁸

The most frequently employed clinical criteria for FMF were established at the Tel-Hashomer Medical Center in Israel and include a schema of major, minor, and supportive criteria.³⁹ These clinical criteria include frequent occurrence of symptoms such as abdominal and thoracic pain, family history, and response to treatment with colchicine.³⁹ However, it should be noted that the sensitivity and specificity of any set of diagnostic criteria vary according to the disease frequency in the population of interest.

Fig. 165.2 (a) Two-dimensional echocardiogram (parasternal long-axis view) showing small posterior pericardial effusion (arrow) in a young woman with familial Mediterranean fever (FMF). (b) Erysipelas-like erythema (ELE) in a patient with FMF. (c) Skin biopsy specimen taken from the site of ELE. Note the predominantly perivascular infiltrate with mixed, predominantly mononuclear cells (hematoxylin-eosin, $\times 1000$).

For patients from high-risk populations with typical clinical manifestations of FMF, the diagnosis still can be made with confidence without the use of DNA studies. Moreover, particularly in cases in which only one mutation is found by genetic testing, clinical judgment will continue to have an important place in the diagnosis of FMF.

Laboratory findings

Laboratory studies performed during FMF attacks show a nonspecific acute-phase response, including leukocytosis, an increased ESR, and elevations in the levels of C-reactive protein (CRP), serum amyloid A (SAA), fibrinogen, and haptoglobin.⁴⁰ Patients may have moderate hypergammaglobulinemia irrespective of whether they are experiencing an attack, and serum immunoglobulin D (IgD) levels can be moderately elevated, especially in patients homozygous for the M694V mutation.⁴¹ Autoantibodies, including antinuclear antibody (ANA), rheumatoid factor (RF), anticardiolipin antibody, and antineutrophil cytoplasmic antibody (ANCA), usually are absent or present only in low titer. The cytoplasmic S100 proteins derived from monocytes and granulocytes are increasingly being used as biomarkers of autoinflammation. S100A8 (MRP-8), S100A9 (MRP-14), and S100A12 (MRP-6) are released during activation of the innate immune system.⁴² S100A12 is released in excessive amounts in FMF, compared with other autoinflammatory diseases, which suggests that neutrophil-derived S100 proteins may be involved in the pathogenesis of this disease.⁴³

Between attacks, FMF patients usually have no residual symptoms. Nevertheless, many FMF patients show persistent elevations in levels of acute-phase reactants, especially CRP and SAA, even between attacks.^{21,44} Moreover, obligate carriers of FMF mutations have increased levels of acute-phase reactants relative to noncarriers.^{21,44}

Complications of untreated disease

Systemic amyloidosis is an extremely serious manifestation of FMF.⁸ It is caused by the deposition of a degradation product of SAA, an acute-phase reactant made by the liver, in a number of different organs. The most common sites of amyloid deposition in FMF are the kidneys, liver, spleen, gastrointestinal tract, lungs, testes, thyroid, and adrenals. Before the advent of colchicine prophylaxis, amyloidosis was a frequent cause of kidney failure and death in FMF patients. Amyloid deposits in FMF seldom occur in the heart, peripheral nerves, or joints (except in the setting of long-term hemodialysis).

Type AA secondary amyloidosis occurs in 13% of Turkish patients.⁴⁵ Frequency of amyloidosis differs among countries, and in a multicenter study the country of recruitment was the most important risk factor for the occurrence of renal amyloidosis.⁴⁶ Individuals with the SAA 1.1/1.1 (α/α) genotype are also at increased risk of amyloidosis.⁴⁷ Kidneys are the most affected organs, and these patients have progressive proteinuria, nephrotic syndrome, and chronic renal failure.⁴⁵ Secondary AA amyloidosis is related to persistently elevated SAA levels. The development of AA amyloidosis is unlikely with low serum concentrations of this protein (less than 4 mg/L).⁴⁸

All FMF patients should be screened regularly for amyloidosis by urinalysis. Patients who have significant proteinuria on repeated urinalyses performed between febrile attacks may require tissue diagnosis.⁴⁹ If treatment is not initiated, the natural history of amyloidosis in FMF is progression to renal failure, usually within 3 to 5 years of diagnosis. In those patients who undergo dialysis or renal transplantation who are not adequately treated, amyloid deposition will continue in the transplanted kidney and other organs, leading to amyloid goiter, malabsorption, and diarrhea due to gastrointestinal deposition, and, occasionally, cardiac involvement.

Treatment

The mainstay of treatment for FMF is daily oral prophylactic colchicine. Dosages of 1.2 to 1.8 mg/day of colchicine prevent both the acute inflammatory attacks of FMF⁵⁰⁻⁵² and the development of systemic amyloidosis.⁵³ Intermittent dosing at the time of attacks is not nearly as effective as is daily administration, and there is no evidence that intermittent colchicine prevents amyloidosis. The major limiting toxicities of colchicine are gastrointestinal—diarrhea, cramping, and bloating—which can be minimized by starting at a low dose and gradually advancing the dose as tolerated, by dividing the daily dose, by using simethicone for flatulence, and by treating the lactose intolerance. Dosages above 1.8-2 mg/day are rarely tolerated for prolonged periods. Colchicine induces a near cessation of FMF attacks in about 70% of patients and provides at least some relief in over 90%.

Rare adverse effects of colchicine include bone marrow suppression and a myoneuropathy that is most often seen in elderly adults with renal insufficiency.⁵⁴ There are anecdotal reports of male infertility due to colchicine,⁵⁵ but most men with FMF are able to father children without discontinuing

the drug. It should also be noted that there are no controlled studies of sperm count or function before and after starting colchicine and that the amyloidosis of FMF may itself cause testicular dysfunction.⁵⁶

In patients taking colchicine regular blood counts and measurement of serum chemistry levels should be performed. Oral colchicine should be continued even in the face of an FMF attack. Patients taking daily oral colchicine should not be given intravenous colchicine in the event of an attack. The concomitant administration of oral and intravenous colchicine has been associated with fatal toxicity.⁵⁷

In patients who have an unsatisfactory response to colchicine or are unable to tolerate the drug, other immunosuppressive treatments have been tried. Corticosteroids are ineffective in either treating or preventing the acute attacks of FMF, and there are anecdotal data that they may even accelerate the amyloidosis of FMF. Interferon alfa-2b (3 million units subcutaneously) may abort FMF attacks if given at the first sensation of an attack.⁵⁸ However, a double-blind study failed to demonstrate a significant therapeutic effect,⁵⁹ and there are no data on the efficacy of interferon in preventing amyloidosis.

Given the cytokine patterns reported in FMF and the major interactions of pyrin and IL-1 β , treatments that target IL-1 have been used in patients unresponsive to or intolerant of therapeutic doses of colchicine.⁶⁰ Case reports have described improvement in FMF using IL-1 blockade with anakinra (Kineret),⁶¹⁻⁶³ and a multicenter trial of rilonacept (Arcalyst), a recombinant IL-1 receptor fusion protein, has recently suggested this anti-IL-1 agent as a treatment option for patients who show no response to colchicine or cannot tolerate it.⁶⁴ There is also anecdotal evidence supporting the use of TNF inhibitors such as etanercept⁶⁵ and infliximab in FMF.^{66,67}

Tumor necrosis factor receptor-associated periodic syndrome

Background

TNF receptor-associated periodic syndrome (TRAPS) (OMIM #142680) is an autosomal dominant, multisystemic, autoinflammatory disorder caused by mutations in *TNFRSF1A*, the gene encoding the 55-kDa receptor for TNF.³ In contrast with FMF, in which there is an evolving relationship between clinical criteria and *MEFV* mutational status, TRAPS was first proposed as a genetic diagnosis. Thus only patients with demonstrable TNF receptor mutations should be categorized as having TRAPS.

Before this terminology was proposed, there had been a number of case descriptions of dominantly inherited periodic fever in families of diverse ethnic backgrounds. Perhaps the best characterized of these was familial Hibernian (Irish) fever first described by Williamson and colleagues⁶⁸ in 1982 in a large pedigree of Irish-Scottish ancestry. The inflammatory attacks observed in this family resembled FMF in some respects, with the presence of abdominal pain, pleurisy, joint pain, an accelerated ESR, and neutrophilia. However, there were important differences,^{68,69} including a much longer duration of attacks; the presence of migratory areas of erythema, swelling and myalgia, conjunctivitis, and periorbital edema; a dominant pattern of inheritance; poor response to colchicine; and a relatively prompt response to corticosteroids.

The subsequent years have vindicated the concept of TRAPS as a distinct clinical entity with a broad ethnic distribution,⁷⁰ and mutations have been reported in patients on every continent. With these later reports, the clinical spectrum of TRAPS has broadened, but a number of common themes have endured.

Genetics and pathophysiology

There are two receptors for the proinflammatory cytokine TNF: a 55-kDa molecule (p55) encoded by *TNFRSF1A* on chromosome arm 12p, and a 75-kDa receptor (p75) encoded by *TNFRSF1B* on chromosome arm 1p. The p55 receptor is expressed on most cell types, whereas expression of the p75 receptor is restricted to leukocytes and endothelial cells. TRAPS is caused by mutations in the p55 receptor; to date there are no known periodic fever patients with mutations in the p75 receptor.

Both TNF receptors belong to a family of membrane proteins with repeating cysteine-rich extracellular motifs. By x-ray crystallography, each cysteine-rich domain (CRD) consists of a loop structure constrained by three disulfide bonds.⁷¹ The p55 receptor has four of these extracellular CRDs, a transmembrane segment, and an intracellular C-terminal death domain (similar in structure to the N-terminal PYD of pyrin) that is actually a cognate interaction motif.

There are at least 26 known mutations at cysteine residues in CRDs 1 and 2, as well as 12 other mutations not occurring at cysteines. To date no TRAPS patients have been reported with transmembrane or intracellular

TNFRSF1A mutations, truncations, null mutations (in which the protein is not expressed), or mutations in the p75 TNF receptor encoded on chromosome 1. Nearly all of the TRAPS mutations catalogued on the Infevers website are found in the first two CRDs, at the N-terminal of the protein,²² which prevents proper disulfide bond formation and protein folding. Systemic amyloidosis is seen more frequently in TRAPS in patients with cysteine substitutions than in those with the other mutations.

The R92Q (glutamine for arginine at codon 92) *TNFRSF1A* variant is seen in 1% to 4% of white control chromosomes,⁷² whereas the P46L (leucine for proline at codon 46) variant is found in approximately 2% of African American and Arab control chromosomes^{72,73} and is seen at an even higher frequency among some sub-Saharan African populations.⁷⁴ Both R92Q and P46L, therefore, meet the formal definition of polymorphisms, and their pathologic significance is controversial since they are found at similar frequencies in individuals coming to periodic fever clinics and in the general populations from which these clinics draw patients. Assuming that these two substitutions do confer susceptibility to autoinflammatory disease, their penetrance (the probability of having disease if the mutation is present) must be low, since the frequency of TRAPS does not approach 1% of the general population. Patients with R92Q have a wider spectrum of clinical manifestations than other TRAPS patients.⁷⁰ Their phenotype is milder, the age at onset is older, and there is an absence of amyloidosis.⁷⁵

The TNF receptor has a cytoplasmic death domain that signals through two pathways, one leading to NF- κ B activation and inflammation, and another leading to caspase activation and apoptosis. Alteration of these pathways provides another possible mechanism for hyperinflammation. NF- κ B activity has been measured in mononuclear cells from patients with the C73R (arginine for cysteine at codon 73) mutation and shown to be elevated.⁷⁶ TNF-induced apoptosis has been measured in neutrophils from TRAPS patients with cysteine mutations and a decrease in apoptosis was noticed,⁷⁷ which potentially interferes with a normal homeostatic mechanism.

Another possible mechanism for inflammation in TRAPS is that mutations at cysteine residues likely cause protein misfolding.¹⁹ Mutant receptors appear to be retained in the endoplasmic reticulum as abnormal disulfide-linked oligomers,¹⁹ which may trigger a ligand-independent (i.e., TNF-independent) proinflammatory state through constitutive activation of NF- κ B,¹⁹ the endoplasmic reticulum stress response, or mitogen-activated protein kinase (MAPK) (see Fig. 165.1c).¹⁹ The proinflammatory state may be further potentiated by autocrine TNF signaling through the remaining wild-type TNF receptor. More recently, additional mechanisms linking innate immune-mediated inflammation with a variety of cellular processes, including protein misfolding, diminished trafficking of mutated TNF receptor 1 to the cell surface, oxidative stress, and mitochondrial dysfunction, have been recognized to play a role in the pathogenesis of TRAPS.¹⁹ Diminished trafficking to the cell surface may further lead to decreased TNF-induced apoptotic signaling since only the p55 receptor and not the p75 receptor delivers apoptotic signals, which could lead to prolonged inflammatory responses. The latter effect may be accentuated by the reduction in ligand binding that appears to occur for certain TRAPS-associated p55 mutations. It has been difficult to document functional abnormalities *in vitro* for the R92Q substitution in trafficking or ligand-binding assays.

Clinical features

As more cases have been diagnosed and the inventory of mutations has grown to currently over 80, the usual duration of episodes in TRAPS remains substantially longer than in the other hereditary periodic fevers. However, shorter attacks lasting less than 7 days can occasionally occur in TRAPS. The interval between attacks in TRAPS, as in FMF, is highly variable among patients and over time in any given patient. Although episodes sometimes develop with no apparent provocation, physical or emotional stress, physical trauma, and menses are sometimes associated with attacks; pregnancy may be associated with an amelioration of symptoms. A small minority of patients experience waxing and waning symptoms on a nearly daily basis. Fever usually heralds the onset of inflammatory episodes and is sometimes the sole manifestation of TRAPS, especially in children. The median age of onset of TRAPS attacks is 3 years.⁷⁰

Pleuritic chest pain and severe abdominal pain, with or without peritoneal signs, occur in TRAPS, as they do in FMF. Early in their disease, patients may undergo exploratory laparotomy, and it is not unusual for patients to develop peritoneal adhesions, presumably the sequelae of recurrent peritoneal inflammation. Symptomatic pericardial involvement is much less common than peritoneal or pleural inflammation. Scrotal pain is uncommon. Arthralgia is more frequent than arthritis in TRAPS and is usually nonerosive and monoarticular, most frequently involving the hips, knees,

or ankles. The chronic arthritis seen in FMF has not been observed in TRAPS.

Features that distinguish TRAPS from FMF include a characteristic migratory myalgia and rash (Fig. 165.3a and b) that is seen at some time in nearly all TRAPS patients. Typically, this occurs as a localized area of cramping muscle pain, often with warmth and tenderness to palpation, and an overlying erythematous, blanchable rash, usually on the torso or the extremities. When it occurs on the limbs, the area of inflammation migrates centrifugally over the course of several days and is often associated with synovitis and effusion as it crosses a joint. Levels of muscle enzymes are not elevated, and magnetic resonance imaging (MRI) demonstrates edema in discrete muscular compartments and intramuscular septa (see Fig. 165.3c). Consistent with the normal muscle enzyme levels, a full-thickness biopsy specimen in one patient demonstrated predominantly panniculitis, fasciitis, and perivascular inflammation, but not involvement of the myofibrils themselves.⁷⁸ In the skin there is a superficial and deep perivascular and interstitial infiltrate of lymphocytes and monocytes.⁷⁹ It is possible that the centrifugal migration represents propagation along fascial planes.

Ocular involvement is another feature that distinguishes TRAPS from FMF.⁷⁰ Approximately 80% of patients experience conjunctivitis, periorbital edema (see Fig. 165.3d), or periorbital pain. Much less commonly, patients may develop iritis or uveitis.

Laboratory findings

The acute attacks of TRAPS are associated with neutrophilia and thrombocytosis (particularly in children) and a global acute-phase response, including an elevated ESR and increased levels of CRP, SAA, haptoglobin, and fibrinogen. Although these parameters may fluctuate with attacks, the elevations often remain even between attacks. Many patients exhibit anemia of chronic disease, polyclonal hypergammaglobulinemia, and low titers of IgM and IgG anticardiolipin antibodies. Tests for ANA, RF, and ANCA usually give negative results. When measured, soluble 55-kDa TNF receptor levels tend to be subnormal between attacks and, in contrast to other inflammatory disorders, increase only modestly during active disease.³

Complications of untreated disease

Systemic amyloidosis occurred in a subset of the families included in the initial description of TRAPS. An analysis of cases followed at the U.S. National Institutes of Health or compiled from the literature found that 14 of 100 patients with TRAPS showed evidence of systemic amyloidosis.⁷² The series was almost evenly divided between patients with nine different mutations involving cysteine residues and patients with seven noncysteine mutations, yet 13 of the 14 patients with amyloidosis had cysteine mutations.

As is the case for FMF, the amyloidosis of TRAPS is secondary to deposition of a presumed cleavage product of SAA, and the tissue distribution of amyloid deposits is similar in the two diseases. The most frequent complication of TRAPS amyloidosis is renal failure, although hepatic failure has also been observed. All TRAPS patients, but particularly those with cysteine mutations, should undergo regular urinalyses to monitor for albuminuria, an early sign of renal amyloidosis.

Treatment

Colchicine is ineffective in preventing the febrile attacks of TRAPS, and it does not prevent the development of systemic amyloidosis, either. Corticosteroids can be used to treat the attacks of TRAPS, but patients frequently require escalating dosages with time, often with diminishing efficacy and serious toxicity. Azathioprine, cyclosporine, thalidomide, cyclophosphamide, chlorambucil, intravenous immunoglobulin, dapsone, and methotrexate have all been tried empirically but have not been found effective.

There has been a growing favorable experience with etanercept, the p75-Fc fusion protein. Initial studies reported a reduction in the frequency and severity of TRAPS attacks with the drug.¹⁹ An open-label study comparing parameters between 3-month baseline, twice-weekly treatment, thrice-weekly treatment, and washout phases demonstrated a significant overall improvement in both clinical and laboratory outcomes.¹⁹ More recently, in a prospective study enrolling 15 patients, treatment with etanercept reduced the frequency and severity of the inflammatory episodes and levels of inflammatory markers, but complete normalization was not achieved.⁸⁰ Other case reports have also documented that etanercept reverses or slows the clinical progression of renal amyloidosis in TRAPS.⁸¹ One patient with the C33Y mutation and amyloidosis was found to have a marked reduction in proteinuria and regression of amyloid as demonstrated on serum amyloid P scanning.⁸² However, a different patient with the C52F mutation experienced a new onset of proteinuria, with amyloid found on renal biopsy, while taking etanercept.⁸³ In TRAPS patients at high risk of amyloidosis, it may be appropriate to use SAA levels in the serum

Fig. 165.3 (a) Erythematous dermal macules and patches in a patient with tumor necrosis factor receptor–associated periodic syndrome (TRAPS). (b) Annular patch with erythematous borders in a patient with TRAPS. (c) Bilateral thigh magnetic resonance image showing fasciitis in a patient with TRAPS and migratory myalgia. (d) Periorbital edema in a child with TRAPS.

to guide therapy. There have recently been reports of initial response to etanercept that later declines, and the drug is of limited success in other patients. Of greater concern are reports of a paradoxical inflammatory reaction in TRAPS patients receiving infliximab.⁸⁴ Reduced apoptosis with increased secretion of proinflammatory cytokines has been observed when patient mononuclear cells are treated with infliximab.¹⁹

Given recent data suggesting that there are TNF-independent pathways of cellular activation in TRAPS, it is not surprising that etanercept often does not completely normalize levels of acute-phase reactants⁸⁵ and that other cytokine inhibitors may be efficacious in at least some patients. In some centers, anti-IL-1 therapy with either the recombinant IL-1 receptor antagonist (IL-1Ra) anakinra or the longer-acting monoclonal anti-IL-1 β antibody canakinumab (Ilaris) have been used with satisfactory responses¹⁹ and have become the treatment of choice. However, failure to respond to treatment with anakinra has also been reported in individual cases.¹⁹

Treatment outcomes for over 100 TRAPS patients were recently reviewed.⁸⁶ For TRAPS patients with relatively infrequent attacks, intermittent prednisone may be a satisfactory alternative. For patients with more frequent attacks, or for whom prednisone is not advisable, intermittent anakinra therapy may be effective. For those patients with frequent attacks or a high risk of amyloidosis, maintenance therapy with etanercept or an IL-1 inhibitor may be necessary, with a preference for IL-1 inhibition

because of the well-documented possible attenuation of etanercept responses over time.

Hyperimmunoglobulinemia D with periodic fever syndrome/mevalonate kinase deficiency

Background

Hyperimmunoglobulinemia D with periodic fever syndrome (HIDS) (OMIM #260920) is a recessively inherited disorder first described in six Dutch patients in 1984.⁸⁷ Although these patients manifested some findings that were consistent with FMF, their abdominal pain was less severe than that usually seen in FMF and they had much more significant lymphadenopathy. In addition, they had constant elevations in serum IgD level and large numbers of IgD+ plasma cells in the bone marrow, findings not usually seen in FMF. For these reasons, van der Meer and colleagues correctly proposed that the condition they described was different from FMF.

In the ensuing 15 years, this clinical syndrome was extensively characterized⁸⁸; it segregates in families as an autosomal recessive trait. Most of the families identified cluster in the Netherlands, France, or neighboring areas of northern Europe. Initial genetic studies ruled out linkage to *MEFV* on chromosome arm 16p.⁸⁹

HIDS is caused by mutations in *MVK*, a gene on the long arm of chromosome 12 that encodes an enzyme in the cholesterol-isoprenoid biosynthetic

pathway.^{90,91} The MVK mutations associated with HIDS leave some residual enzyme activity, whereas more severe loss-of-function mutations lead to mevalonic aciduria, a potentially fatal condition accompanied by significant developmental and cognitive abnormalities as well as recurrent fevers.

HIDS remains a relatively rare condition,^{92,93} occurring at a much lower frequency than FMF or TRAPS in the mixed population of the United States. Approximately 0.6% of the population in the Netherlands are carriers for the V377I (isoleucine for valine at codon 377) mutation, with haplotype data supporting a founder effect.^{93,94} Analysis of the MVK genotypes of HIDS patients indicates an underrepresentation of V377I homozygotes relative to the expected Hardy-Weinberg distribution, which suggests a milder phenotype or reduced penetrance for V377I homozygotes.⁹⁴

In general, elevations in serum IgD levels and mutations in MVK correlate well. However, there are occasional patients with periodic fevers and HIDS-associated MVK mutations who have normal IgD levels,^{90,95,96} and conversely there is a significant number of patients with periodic fever and elevated serum IgD levels who have no demonstrable MVK mutations.^{97,98} These observations suggest a somewhat more complicated picture than simple equivalence of the HIDS clinical phenotype with specific MVK mutations.⁹⁹ For this reason, some experts prefer the term *mevalonate kinase deficiency* to describe those patients with a recurrent fever syndrome and MVK mutations who do not have the more severe developmental manifestations of mevalonic aciduria.

Genetics and pathophysiology

HIDS is caused by recessively inherited mutations in MVK, the gene for mevalonate kinase (MK),^{90,91} an enzyme that catalyzes the conversion of mevalonic acid to 5-phosphomevalonic acid. Currently over 160 MVK variants, most of them missense substitutions, are listed on the Infevers website; more than 30 are thought to be disease causing.¹⁰ Nearly all mutation-positive HIDS patients harbor at least one copy of the substitution V377I,¹⁰⁰ and the substitution I268T (threonine for isoleucine at codon 268) is the second most common mutation.¹⁰⁰

Lymphocytes and fibroblasts from HIDS patients exhibit reduced but not absent MK enzymatic activity. In contrast, patients with the much more severe mevalonic aciduria have almost no residual enzymatic activity. These latter patients experience many of the inflammatory manifestations of HIDS but also develop dysmorphic facies, cataracts, cerebellar ataxia, cerebral atrophy, mental retardation, hypotonia, and failure to thrive.^{101,102} The MVK mutations causing HIDS are distinct from those causing mevalonic aciduria, although there is some overlap. HIDS-associated mutations are mainly missense variants distributed throughout the coding region of the gene, whereas mevalonic aciduria-associated mutations are concentrated between residues 243 and 334.¹⁰⁰

Among HIDS patients there is no correlation between MK activity and severity of disease.⁹⁸ Moreover, the biochemical connection between MK mutations and inflammation is still unclear. The crystal structure of rat MK has been determined and V377I, the most common mutation, is spatially far removed from the catalytic site of the enzyme.¹⁰³ However, this mutation may destabilize the protein and thereby lead to reduced enzyme activity.⁹⁰ Cholesterol levels in HIDS patients are usually in the low-normal range, which suggests that unavailability of cholesterol is not the mechanism of inflammatory episodes.¹⁰²

Although early studies suggested that the proinflammatory state of HIDS is induced by the accumulation of mevalonic acid,¹⁰⁴ the prevailing current hypothesis is that inflammation is caused by a shortage of isoprenoids.^{105,106} *In vitro* data obtained using leukocytes of HIDS patients suggest that farnesol or geranyl-geraniol compounds can reverse accentuated IL-1 β secretion¹⁰⁷ and that inhibitors of sterol biosynthesis, which favor nonsterol isoprenoid biosynthesis, also reduce IL-1 β secretion by HIDS leukocytes.¹⁰⁸ There is also a defect in apoptosis in the peripheral blood leukocytes of HIDS patients.¹⁰⁹

A mouse model of HIDS was generated by deleting a single MVK allele, and this resulted in increased blood levels of mevalonate and IgD.¹¹⁰ It is unlikely, however, that elevation in IgD level itself is the cause of fever and inflammation; there are a number of other conditions, including diabetes mellitus, pregnancy, and cigarette smoking, in which IgD levels are modestly increased⁸⁸ but there are no symptoms compatible with HIDS.

Clinical features

Typically, HIDS manifests very early in life, with a median age of onset of 6 months.⁸⁸ It is not unusual for childhood vaccinations to precipitate febrile episodes. Other provocative factors include infections, emotional stress, trauma, and surgery, but in many instances there is no obvious trigger. Patients frequently report some type of premonitory symptoms, and the usual attacks of HIDS last approximately 3 to 7 days. Headache is a frequent

Fig. 165.4 Diffuse erythematous and purpuric maculopapular rash in a child with hyperimmunoglobulinemia D with periodic fever syndrome.

but nonspecific concomitant of HIDS attacks. As with the other recurrent fever syndromes, the attacks are usually not truly periodic but rather episodic, and the inter-attack interval can vary greatly both among patients and over time for any given patient. With increasing age there is a tendency for the attacks to become less frequent and less severe.⁸⁸

The majority of HIDS patients have episodes of abdominal pain, sometimes severe enough to warrant exploratory laparotomy. Unexplained adhesions are sometimes found, consistent with a history of peritoneal inflammation.⁸⁸ In contrast with FMF, diarrhea is often seen with HIDS attacks, usually toward the end of the episode. Vomiting is also common. Scrotal pain has also been reported.⁹⁶ Pleurisy and pericardial involvements are rare in HIDS.

Arthralgia is very common during HIDS episodes, and arthritis was documented in nearly 70% of patients in one series.⁸⁸ Mucocutaneous lesions are common during HIDS attacks.^{88,111} Crops of erythematous macules, ranging from 0.5 to 2 cm in diameter and sometimes affecting the palms and soles, are the most frequent skin manifestation of HIDS (Fig. 165.4). Other dermatologic findings include erythematous papules and nodules, urticaria, annular erythema, and purpura. A large series of HIDS skin biopsy specimens showed swelling of endothelial cells, perivascular edema, and mixed cellular perivascular infiltrates.¹¹¹ Painful aphthous ulcers of the mouth or vagina are also sometimes seen in HIDS.⁹²

Diffuse lymphadenopathy is one of the clinical features that distinguish HIDS from other hereditary recurrent fevers.^{88,92} Swelling of the cervical nodes fluctuates with attacks; inguinal, axillary, and mesenteric adenopathy may also be present. Histologic examination shows nonspecific reactive lymphadenitis. Splenomegaly is also frequently found in children with HIDS. Results of a comprehensive overview of a large cohort of HIDS patients begun in 1994 were published by the International HIDS Study Group.¹¹² The clinical findings usually associated with HIDS actually correlate better with the presence of MVK mutations than with high IgD levels.¹¹³

Laboratory findings

During their febrile episodes, HIDS patients manifest the same vigorous but nonspecific acute-phase response seen in the other hereditary recurrent fevers. This includes increased ESR and CRP, SAA, haptoglobin, and fibrinogen levels. There is also leukocytosis with a left shift. Levels of several cytokines, including interferon- γ (IFN- γ) TNF, and IL-6, are increased in the serum during attacks.^{114,115} The urinary level of neopterin, a marker for cellular immune activation, is also increased during febrile attacks.¹¹⁵ Urinary

mevalonate levels correlate well with HIDS episodes. Autoantibodies are generally not found in HIDS.

Before the underlying gene was identified, measurement of an elevated level of serum IgD (more than 100 IU/mL or more than 10 mg/dL) on two or more occasions at least 1 month apart was required for the diagnosis of HIDS.⁸⁸ Levels do not fluctuate with attacks, nor do they correlate with overall disease severity across individuals or in a given individual over time. IgA levels (primarily of the IgA1 subclass) are also increased in over 80% of patients with HIDS.

Based on the genetics and biochemistry of MVK, new diagnostic approaches are now possible: mutational screening, quantitation of urinary mevalonic acid, and measurement of MK activity in cultured fibroblasts or leukocytes.

Mutational screening is currently the most frequent used way of confirming the diagnosis of HIDS. Since a large percentage of HIDS patients have at least one copy of either the V377I or I268T mutation, it is cost effective to screen for these mutations first before undertaking a more comprehensive sequencing effort.

Urinary mevalonate levels can be measured by routine gas chromatography/mass spectroscopy or by isotope dilution methods.^{95,102} MK enzymatic assay in cultured fibroblasts or leukocytes is probably the most technically demanding of the biochemical approaches to confirming a diagnosis of HIDS.

As noted earlier, there are a small number of patients who have recurrent fevers and MVK mutations but normal IgD levels.^{90,95} Current practice is perhaps to use the term *mevalonate kinase deficiency* in such patients. There are somewhat larger numbers of patients who have increased serum IgD levels but no MVK mutations.⁹⁷⁻⁹⁹ Such patients generally are not said to have HIDS. Further complicating matters, there can be modest elevations in the serum IgD level in a minority of patients with FMF^{41,116} and TRAPS,⁶⁹ as well as in some patients with the syndrome of periodic fever, aphthous stomatitis, pharyngitis, and cervical adenopathy (PFAPA).¹¹⁷

The differential diagnosis for HIDS is broad and includes FMF, TRAPS, PFAPA, adult-onset Still disease, juvenile idiopathic arthritis, rheumatic fever, and Behçet disease.¹¹² When confronted with a patient with unexplained recurrent fever in whom FMF and TRAPS are unlikely or have been ruled out, most experts would now proceed to genetic testing, with or without measurement of serum IgD levels. For HIDS screening, patients can be evaluated for fulfillment of at least one of the following two clinical criteria: (1) age of onset of less than 5 years, and (2) joint pains during attacks and attack duration of less than 14 days.¹¹⁸ The nature of the disorder in patients with definite IgD elevations but normal results on mutational screens remain to be understood.

Complications of untreated disease

In contrast with the other hereditary periodic fevers, amyloidosis is uncommon in HIDS patients⁹² and has only recently been reported.^{119,120} It is unlikely that this difference in the frequency of amyloidosis represents a difference in the severity of inflammation integrated over time, since SAA levels are markedly elevated during attacks, and many patients exhibit subclinical inflammation even between their attacks.¹²¹ In the absence of amyloidosis, the overwhelming majority of patients with HIDS have a normal life expectancy.⁸⁸

Treatment

There is currently no consensus regarding the treatment of HIDS. Nonsteroidal antiinflammatory drugs (NSAIDs) may help to control fever and arthralgia. Corticosteroids may help to control attacks in some patients, but long-term toxicity is a major concern, especially in children. There have been mixed results with colchicine, intravenous γ -globulin, and cyclosporine.⁹² A small, double-blind, crossover trial of thalidomide demonstrated modest decreases in levels of acute-phase reactants but no effect on the attack rate.¹²²

Current therapeutic strategies in HIDS have focused on the mevalonate pathway and on cytokine inhibition.⁸⁶ Paradoxically, trials of hydroxymethylglutaryl-coenzyme A reductase inhibitors (statins) have suggested a potential benefit, most notably with simvastatin.^{92,104} However, in a French survey involving 50 patients, all 8 patients who received simvastatin failed to respond to this treatment,¹²³ and in the International HIDS Study Group multicenter study, 12 of 18 patients failed to respond.¹¹² An open-label use of the TNF inhibitor etanercept produced substantial improvement in two patients with HIDS,¹²⁴ although such a response is not universal.^{125,126} The use of IL-1 inhibitors may represent yet another possible strategy.¹²⁵ Recently, the efficacy of anti-IL-1 drugs (anakinra and canakinumab) was assessed in a study that included 11 HIDS patients. Complete and partial remission were observed in 4 and 7 patients, respectively.¹²⁷

MONOGENIC SYNDROMES WITH MUTATIONS IN THE INTERLEUKIN-1 PATHWAY

The cryopyrinopathies (familial cold autoinflammatory syndrome, Muckle-Wells syndrome, and neonatal-onset multisystem inflammatory disease)

Background

The cryopyrinopathies, or cryopyrin-associated periodic syndromes (CAPS), comprise a clinical continuum of three historically defined diseases: familial cold autoinflammatory syndrome (FCAS; OMIM #120100), Muckle-Wells syndrome (MWS; OMIM #191900), and neonatal-onset multisystem inflammatory disease (NOMID), also known as *chronic infantile neurologic cutaneous and articular (CINCA) syndrome* (OMIM #607115).¹²⁸⁻¹³⁰ The cryopyrinopathies are all caused by mutations in *NLRP3/CIAS1*, which led to the recognition that a common pathogenic pathway must underlie these conditions and that they present as a disease severity spectrum with FCAS at the clinically milder end and NOMID at the clinically severe end of the severity spectrum. Although the inheritance pattern in FCAS and MWS is usually familial,¹³¹ the disease is sporadic in patients with the clinically severe phenotype of NOMID/CINCA.¹²⁸ The sporadic inheritance pattern in NOMID/CINCA is accounted for by the severe phenotype of untreated patients, which results in their inability to reproduce.¹²⁸ However, with the initiation of early IL-1-blocking therapy, the face of NOMID is rapidly changing, and patients who used to have severe disease can have normal or close to normal lives. The *NLRP3* gene encodes the protein cryopyrin, a component of an IL-1 β -activating complex, the NLRP3 inflammasome. This finding led to a decade of intense investigation not only into the role of IL-1 in the rare disorders CAPS and other autoinflammatory diseases, but also into its role in a large group of common disorders, including gout, diabetes mellitus, coronary artery disease, and Alzheimer disease, to name only a few.

Genetics and pathophysiology

There are few epidemiologic studies of CAPS; prevalence estimates of 1 to 2 patients per 1,000,000 people in Europe and the United States are based on the known cases treated in centers studying these patients.

FCAS, MWS, and the sporadic disease NOMID/CINCA are all caused by autosomal dominant gain-of-function mutations in *NLRP3*, which is also called *NALP3*, *CIAS1*, and *PYPAF1*. *NLRP3* encodes a protein that is expressed in monocytes, granulocytes, T cells, chondrocytes, keratinocytes, and probably other cells.¹³¹⁻¹³³ Over 100 disease-causing mutations have been reported in the Infevers database²²; 90% are located in exon 3 of the gene, which encodes the NACHT domain of the protein.^{13,131} About 50% of NOMID/CINCA patients and a much smaller percentage of recognized patients with FCAS and MWS do not have germline mutations in *NLRP3*, but recently, 70% of these presumed mutation-negative patients were found to have somatic mosaicism in *NLRP3*. In the majority of cases, the disease was milder in patients with somatic mosaicism than in patients with germline mutations.^{134,135}

The NLRP3 inflammasome and interleukin-1 β activation and secretion

As noted earlier, *NLRP3/CIAS1* encodes the protein cryopyrin, which belongs to the NOD-like receptor (NLR) family of proteins; these proteins are intracellular sensors of molecular danger signals and are characterized by the presence of a central nucleotide-binding and oligomerization (NACHT) domain, a C-terminal leucine-rich repeat domain, and either an N-terminal caspase activation and recruitment domain (CARD) or a pyrin domain (PYD); cryopyrin has a PYD. Cryopyrin forms a multimolecular complex, the NLRP3 inflammasome,^{16,17} via the recruitment of ASC, CARDINAL, and two molecules of the proinflammatory protease procaspase-1 (Fig. 165.5).¹⁷ The assembly of the NLRP3 inflammasome is mediated by self-oligomerization, permitting autocleavage and formation of active caspase-1.¹³⁶ Active caspase-1 cleaves pro-IL-1 β and pro-IL-18 into their biologically active forms. IL-1 β is a potent proinflammatory cytokine; its production, activation, and secretion are tightly regulated. The NLRP3 inflammasome provides a molecular link between the recognition of danger and the activation of the proinflammatory cytokine IL-1 β as an early "alarm/response" cytokine (see Fig. 165.5).¹³⁷

The NLRP3 inflammasome can be activated by a number of chemically and structurally diverse exogenous and endogenous or host-derived molecules. Exogenous stimuli that trigger inflammasome activation include whole pathogens; pathogen-associated molecular patterns such as

Fig. 165.5 (1) The first step in NLRP3 activation is a signal by pattern recognition receptors, most commonly Toll-like receptors (TLRs) that activate transcription of NLRP3 and pro-interleukin-1 β (pro-IL-1 β) through nuclear factor- κ B (NF- κ B). NLRP3 is also activated by de-ubiquitination. (2) The second step is NLRP3 activation per se. At least one of three events is usually required: potassium efflux, cathepsin B release from lysosomes, and production of reactive oxygen species (ROS). Two direct ROS-related NLRP3 ligands have recently been proposed: TXNIP, which is released from the redox system, and oxidized mitochondrial DNA. Mitochondria and mitochondrial ROS seem to play an important role and can be influenced by calcium signaling. Through removal of ROS-producing dysfunctional mitochondria, NLRP3 activation is downregulated by autophagy. The second messenger cyclic adenosine monophosphate (cAMP) can also bind directly to NLRP3 and inhibit its activation. Extracellular calcium decreases cAMP through CASR signaling. Kinase signaling positively regulates NLRP3 activation through PKR, which directly interacts with NLRP3, whereas Syk kinase activity is required for NLRP3 activation in response to specific ligands such as *Candida albicans*. (3) NLRP3 activation further triggers the assembly of active inflammasome complexes containing ASC (apoptosis-associated specklike protein with a caspase recruitment domain) and procaspase-1. Endogenous and viral pyrin-only proteins (POPs) can interfere with inflammasome assembly, whereas GBP5 selectively promotes NLRP3-dependent ASC oligomerization. (4) Finally, inflammasome formation leads to the processing and activation of caspase-1, which cleaves the pro forms of interleukin-1 β (IL-1 β) and IL-18; the result is the release of the mature cytokines and induction of cell death by pyroptosis. ATP, adenosine triphosphate; CPPD, calcium pyrophosphate dehydrate; DAMPs, damage-associated molecular patterns; EBV, Epstein-Barr virus; ER, endoplasmic reticulum; LPS, lipopolysaccharide; NLR, NOD-like receptor; PAMPs, pathogen-associated molecular patterns; TNF- α , tumor necrosis factor- α ; UVB, ultraviolet B light. (Adapted from Haneklaus M, O'Neill LA, Coll RC. Modulatory mechanisms controlling the NLRP3 inflammasome in inflammation: recent developments. *Curr Opin Immunol* 2013;25:40-5.)

lipopolysaccharide; (viral) nucleic acids; muramyl dipeptide; toxins; and environmental stimuli such as asbestos and silica. Endogenous triggers include indicators of cellular injury, such as extracellular adenosine triphosphate, and indicators of metabolic stress, including elevated extracellular glucose levels, monosodium urate, calcium pyrophosphate dehydrate crystals, β -amyloid fibrils, cholesterol crystals, and pancreatic amyloid peptide. Proposed pathways leading to inflammasome activation are depicted in Figure 165.5.¹³⁸

It has been recognized that the multitude of inflammasome-activating stimuli cannot possibly bind to the NLRP3 inflammasome, which raises the question of a common upstream pathway. The release of lysosomal contents during lysosomal rupture that is mediated by phagocytosed large inorganic materials, leads to the production of reactive oxygen species (ROS). It has also been suggested that mitochondrial ROS might trigger inflammasome activation and ion fluxes such as K⁺ efflux and the release of Ca²⁺ from the endoplasmic reticulum. (see Fig. 165.5).¹³⁸

Recently, oxidized mitochondrial DNA released from damaged mitochondria has been suggested to regulate NLRP3 activation through direct binding to cryopyrin; this not only further highlights the central role of the mitochondria but may be the common resulting pathway leading to inflammasome activation, which can be regulated by the mechanisms described earlier (see Fig. 165.5).¹³⁸

Hypotheses about how disease-causing gain-of-function mutations in NLRP3 can lead to inflammasome activation suggest that inflammasomes with the gain-of-function mutations release increased amounts of IL-1 β ,¹³⁹ which may be mediated through an increase in the redox state in monocytes carrying mutant cryopyrin. This, in turn, promotes more rapid caspase activation, IL-1 maturation, and secretion.¹⁴⁰ Mutations in NLRP3 cause decreased binding of cyclic adenosine monophosphate,¹⁴¹ a negative regulator of NLRP3 activation, which suggests that the mutations can modify inflammasome activation through several mechanisms (see Fig. 165.5).

Clinical features

All CAPS patients have episodes of fever, urticaria-like rash (Fig. 165.6a), conjunctivitis, arthralgia, and elevations in levels of acute-phase reactants but differ in the spectrum of multiorgan disease manifestations and in long-term morbidity and mortality.¹⁴² The skin rash is often the first noticeable disease manifestation; it is often present at birth or develops within hours of birth, but in FCAS patients it can first develop later in childhood. Other cutaneous manifestations include soft, doughy palms, soles, fingers, and toes, and clubbing of the fingernails without any evidence of pulmonary disease. Unlike in true familial and acquired cold urticaria, the ice cube test yields negative results in CAPS patients. Histologically, skin biopsy specimens show a dermal polymorphonuclear perivascular infiltrate, which is distinct from the lymphocytic and eosinophilic infiltrate found in classical allergic urticaria.¹⁴² The fever pattern in these disorders varies with the disease severity. Although in FCAS the inflammatory attacks are induced by cold exposure and subside within several hours, often to a state without residual inflammation, NOMID patients have continuous, often low-grade fever with disease exacerbations.¹⁴³ The severity

and specific disease manifestations of CAPS are discussed in the following sections.

Familial cold autoinflammatory syndrome

FCAS is at the milder end of the spectrum of CAPS.¹²⁹ FCAS flares are triggered by cold exposure and present with low-grade fever (93% of patients), polyarthralgia (96%), and urticarial rash (100%) that often start within 2 hours of cold exposure and last 12 to 48 hours.^{133,144} Other common features of FCAS include conjunctivitis (mostly with the attacks), profuse sweating, and dizziness, and headaches and nausea are also seen.¹³³ Rarely, FCAS patients have recurrent fever, mild arthralgia, inflammatory myocardiopathy, nephropathy, and thyroiditis as the only manifestation.¹⁴⁵ FCAS symptoms typically appear in early childhood, but a first presentation later in life is also seen.

Muckle-Wells syndrome

In 1962, Muckle and Wells described a familial syndrome with urticaria, hearing loss, and amyloidosis in nine individuals.¹⁴⁶ Patients with MWS have similar symptoms of fevers, urticaria-like rash, joint pain, conjunctivitis, and headaches, and recurrent arthritis and conjunctivitis episodes occur frequently.^{147,148} However, in contrast to patients with FCAS, these symptoms can be continuous and are not typically precipitated by cold exposure. During severe attacks, patients often complain of headache and have aseptic meningitis, and some MWS patients have papilledema. Episcleritis and optic disc edema can also be seen in MWS. Sensorineural hearing loss is the most typical clinical feature in MWS and is due to chronic inflammation of the inner ear, which likely leads to damage of the organ of Corti.¹⁴⁸ Significant hearing loss typically develops in the second to third decade of life in these patients.

Neonatal-onset multisystem inflammatory disease/chronic infantile neurologic cutaneous and articular syndrome

NOMID/CINCA is at the most severe end of the CAPS spectrum and was first described in 1981.¹⁴⁹ NOMID is diagnosed clinically based on the

Fig. 165.6 (a) Urticarial rash in a patient with cryopyrin-associated periodic syndrome (CAPS)—Muckle-Wells syndrome. (b) Papilledema in a patient with CAPS—neonatal-onset multisystem inflammatory disease (NOMID). (c) Severe hydrocephalus in a patient with CAPS-NOMID. (d) Magnetic resonance image (MRI) showing cochlear enhancement in a patient with CAPS-NOMID. (e) MRI after treatment with anakinra showing resolution of the cochlear enhancement. (f) Typical patellar enlargement in a patient with CAPS-NOMID. (g) Knee MRI showing epiphyseal edema in a patient with CAPS-NOMID.

presence of characteristic features, which include neutrophilic urticaria, central nervous system (CNS) manifestations such as papilledema (see Fig. 165.6b) and aseptic meningitis with increased intracranial pressure, sensorineural hearing loss, and/or characteristic bony overgrowth. Continuous, often low-grade fevers, cutaneous rash, aseptic meningitis, and arthropathy start in the first weeks of life; exacerbations and flares are frequent.¹⁵⁰ Neutrophilic urticarial skin lesions are found in almost all patients. Neurologic involvement is a diagnostic feature of NOMID and is characterized by chronic aseptic neutrophilic meningitis that causes chronic irritability, headache, and seizures.^{150,151} Severely affected children develop hydrocephalus (see Fig. 165.6c), brain atrophy, and cognitive impairment. Patients typically develop sensorineural hearing loss within the first year of life, and cochlear enhancement is seen on MRI and suggests cochleitis as the cause of hearing loss (see Fig. 165.6d and e).

The most common inflammatory eye manifestation is conjunctivitis. Optic nerve atrophy is the primary cause of progressive vision loss, but anterior and rarely posterior uveitis can contribute.¹⁵⁰ Cognitive delay is multifactorial and due to perinatal insult and the degree of CNS inflammation.

Most NOMID patients (50% to 70%) have a deforming arthropathy that results in abnormal epiphyseal calcification, cartilage overgrowth, and joint deformities.¹⁵² Most commonly involved are the epiphyses of the distal femur and proximal tibia of the knee, which frequently leads to joint deformities and contractures. Premature patellar ossification and patellar overgrowth is a typical finding in NOMID (see Fig. 165.6f and g).¹⁵¹

Laboratory findings

Abnormal laboratory findings include marked leukocytosis with neutrophilia and thrombocytosis, anemia, and increased acute-phase reactants, such as ESR and CRP level.¹⁵⁰

Careful assessment of the CNS disease in NOMID/CINCA is often necessary, including lumbar punctures to monitor increased intracranial pressure, neutrophilic leukocytosis, and elevation of protein level in the cerebrospinal fluid. Leptomeningeal enhancement to various degrees is seen on high-resolution gadolinium-enhanced MRI, confirming the diagnosis of aseptic meningitis. The enhancement of the cochlea in the inner ear has indicated the inflammatory origin of the hearing loss in MWS and NOMID, and special cuts through the inner ear are useful in specialized clinical settings to follow inner ear inflammation and to adjust therapy. Radiographs of the long bones in patients with NOMID indicate the location of epiphyseal lesions, are used to monitor the bony overgrowth, and help to determine the need for surgical interventions such as osteotomies and stapling of the growth plates. MRI is used to rule out bone tumors and establish the presence of synovial inflammation, which is usually fairly non-impressive in most NOMID patients.

The diagnosis of CAPS is based on the clinical characteristics. The presence of *CIAS1/NLRP3* mutations is confirmatory but is not necessary to make the diagnosis and initiate appropriate therapy because mutation-positive and mutation-negative patients respond equally to IL-1-blocking therapy.¹⁵⁰ Although the majority of patients with FCAS and MWS carry germline mutations in *NLRP3*, the diagnosis of MWS can often be made on clinical grounds and should be considered in patients who have classic neutrophilic urticaria, hearing loss, and familial disease. In “mutation-negative” NOMID patients, somatic mutations were found to cause disease in about 70% of patients; somatic mutations are detected by either subcloning or deep sequencing; clinical assays to test for somatic mutations are currently not widely available, and relying on them could unnecessarily delay a therapeutic intervention.^{134,135} Given the significant benefit from IL-1-blocking therapies, a treatment challenge might help to confirm the clinical suspicion of CAPS.

Complications of untreated disease

As reported for the periodic fever syndromes, amyloidosis is also a feared complication of CAPS. In contrast to patients with FCAS, in whom secondary amyloidosis is rarely observed and is reported to occur in fewer than 2% of cases,¹⁵³ amyloidosis has frequently been described in untreated patients with MWS living in Europe, affecting 25% to 33% of patients.¹⁵⁴ Although amyloidosis in NOMID patients is not frequently reported in the literature, untreated NOMID patients with prolonged elevation of inflammatory markers are also at risk of development of amyloidosis.

Permanent organ damage related to CAPS is most prominent in NOMID and to a lesser extent in MWS and develops as a consequence of persistent inflammation in the affected organs.¹⁵⁵ Ongoing cochlear inflammation leads to sensorineural hearing loss, which develops in NOMID patients in the first decade of life and in MWS patients often in the second or third decade of life. Chronic aseptic meningitis leads to the development of increased

intracranial pressures and hydrocephalus, brain atrophy, and cognitive impairment. Chronic papilledema leads to optic nerve atrophy and progressive vision loss. Patients with hydrocephalus often have a typical facies, with frontal bossing, large cephalic perimeter, and saddle nose.^{150,151} The bony deformities were described earlier and usually do not resolve with IL-1-blocking therapies.^{132,156} In NOMID patients osseous lesions can lead to significant disability, including the development of severe limb-length discrepancies, bony overgrowth resulting in bone deformities, and joint contractures often requiring corrective surgery.

Treatment

Despite clinical heterogeneity, all patients with FCAS, MWS, and NOMID respond dramatically and invariably to IL-1 blockade. Studies have shown the efficacy and safety of anakinra (recombinant IL-1Ra) and the long-acting drugs rilonacept (IL-1 Trap, a fusion protein of the IL-1 receptor and the Fc portion of IgG) and canakinumab (an IL-1 β -blocking antibody).^{155,157,158,159} All patients show rapid improvement in clinical and laboratory parameters with treatment, which has led to the approval currently of three anti-IL-1 agents for the treatment of CAPS.

Although treatment of some patients with FCAS is aimed at improving the cold-induced symptoms by preventing cold exposure, optimal treatment with an IL-1-blocking agent (anakinra, rilonacept, or canakinumab) leads to complete resolution of symptoms in most cases and is the treatment of choice.^{160,161} In patients with MWS and NOMID, who develop organ damage from untreated disease, optimal IL-1-inhibiting therapy needs to be initiated early to prevent the development and progression of organ damage.¹⁵⁵ Recombinant IL-1Ra (anakinra) has been used for treatment of NOMID for over 10 years.¹⁵⁰ All patients show a rapid response to anakinra with dramatic improvement of inflammatory symptoms, fever, skin rash, and acute-phase reactants.¹⁵⁰ Notably, only bony overgrowth changes progress on treatment, which suggests that once the lesion is established, continuation of its growth is likely independent of IL-1.

Although dosages of IL-1-blocking drugs used to suppress disease activity in FCAS patients are typically lower than those that effectively suppress inflammation in NOMID patients, careful monitoring of the inflammatory disease lesions is often necessary to establish optimal individual treatment dosages to control organ inflammation, particularly CNS and inner ear inflammation.¹⁶² Reports of sustained responses to the IL-1-blocking therapies anakinra,^{155,163} rilonacept,^{158,164} and canakinumab¹⁶⁵ have recently been published.

The resolution of symptoms and the achievement of inflammatory remission not only in the blood but also in specific organs provided an important proof that the systemic and organ-specific inflammation seen in these disorders is IL-1 β dependent. The success of the treatment of CAPS with IL-1 blockade provided an example of how understanding the pathophysiologic processes responsible for inflammatory diseases can lead to rational targeting of the effector pathways.

Deficiency of interleukin-1 receptor antagonist

Genetics and pathophysiology

Deficiency of IL-1 receptor antagonist (DIRA; OMIM #612852) was first described in 2009. It is caused by autosomal recessive loss-of-function mutations in the *IL1RN* gene, which encodes IL-1Ra.^{166,167} Clinical descriptions of DIRA were published as early as 1993.¹⁶⁸ Nine disease-causing mutations have been reported to result in DIRA²²: three missense mutations, three nonsense mutations, two small deletions (2 and 15 base pairs), and one large genomic deletion (175 kilobases).^{6,169}

The mutations in *IL1RN* are likely founder mutations and have so far been described in Newfoundland, the Netherlands, Lebanon, Turkey, northern Puerto Rico, and Brazil. The incidence and prevalence of DIRA are unknown, with only about 40 cases reported or diagnosed worldwide so far. The allele frequency for the mutation could be estimated in the founder populations as 0.2% in Newfoundland and 1.3% in northern Puerto Rico.

IL-1Ra competes with the proinflammatory cytokines IL-1 α and IL-1 β for binding sites on the IL-1 type I receptor and prevents IL-1 signaling. The homozygous 3'-truncation mutants of *IL1RN* and the genomic deletion, including the *IL1RN* locus seen in patients with DIRA, lead to the production of a nonfunctional IL-1Ra protein or the absence of the protein, respectively, and the unopposed signaling leads to increased production of proinflammatory cytokines and chemokines, including IL-6, IL-8, MIP-1 α , and TNF.^{166,167}

Clinical features

DIRA patients have early-onset pustular dermatitis and multifocal osteomyelitis and periosteitis, associated with marked elevation in the levels of acute-phase reactants.^{166,167} Pustular skin lesions may be sparse, occur in

Fig. 165.7 (a) Pustular skin lesions in a patient with deficiency of interleukin-1 receptor antagonist (DIRA). (b) Erythematous and scaly skin rash in a patient with DIRA. (c) Spine magnetic resonance image showing destruction of vertebral bodies and intense kyphosis due to osteomyelitis in a patient with DIRA.

crops, or develop into a severe, generalized pustular dermatitis that at times can be ichthyosis-like (Fig. 165.7a and b).^{166,170} Histologic findings on skin biopsy include corneal pustules, acanthosis, and hyperkeratosis.^{166,170} Nail changes with onychomadesis are seen in very young untreated children.¹⁶⁶ All DIRA patients identified so far have had osteomyelitis, which is clinically characterized by pain on manipulation and periarticular swelling. Typical radiographic features are widened ribs and clavicles, as well as multifocal osteolytic lesions seen mainly in long bones.^{166,167,170} Heterotopic ossification or periosteal cloaking around the proximal femoral metaphysis is seen in very young children.

Fever is not frequent and often low grade when present and can be related to secondary skin infections in untreated patients.^{166,171} Recently, a disease-causing mutation was found to lead to intrauterine disease onset, systemic involvement resembling neonatal sepsis, and death in a premature newborn.¹⁶⁹

Laboratory findings

Patients with DIRA have persistent or recurrent increases in inflammatory markers (CRP and ESR), leukocytosis, and normocytic and normochromic anemia.

Complications of untreated disease

Untreated chronic osteomyelitis may lead to bone deformities and particularly vertebral destruction (see Fig. 165.7c); all infants should be screened for atlantoaxial subluxation due to odontoid destruction, which can lead to neck instability.¹⁷⁰ Less frequently observed manifestations in DIRA patients with untreated disease include interstitial lung disease and, rarely, CNS vasculitis.

Treatment

Recombinant IL-1Ra (anakinra) has been used in DIRA with impressive results.^{166,170} Treatment with anakinra leads to rapid resolution of symptoms and normalization of acute-phase reactants, and prevents the recurrence of both skin and bone manifestations.^{166,170}

SYNDROMES PRESENTING WITH GRANULOMATOUS SKIN LESIONS AND MINIMAL OR LOW-GRADE FEVER ATTACKS

Pediatric granulomatous arthritis (Blau syndrome/early-onset sarcoidosis)

Background

In 1985 Blau and coworkers described an autosomal dominant inherited disorder characterized by a clinical triad of chronic arthritis, granulomatous

dermatitis, and recurrent uveitis starting before the age of 4 years, which was called *Blau syndrome*. In 1996 Tromp and colleagues¹⁷² mapped the genetic cause of the disease to chromosome 16 (16q12.1-13), and in 2001 Miceli-Richard and coworkers¹⁷³ discovered that missense mutations in the *NOD2/CARD15* gene caused this clinical phenotype. In 2005 mutations in the same gene were found to cause a sporadic disease, early-onset sarcoidosis, with clinical resemblance.^{174,175} To reflect the fact that the familial and the sporadic form are the same disease, the disease spectrum is referred to as *pediatric granulomatous arthritis* (PGA).¹⁷⁶

Genetics and pathophysiology

PGA (OMIM #186580) is caused by autosomal dominant gain-of-function mutations in the NACHT domain (exon 4) of *NOD2/CARD15*.^{13,177} PGA can be inherited in an autosomal dominant manner, and familial cases have traditionally been called *Blau syndrome*. However, mutations can occur sporadically, and in these instances, the disease has been referred to as *early-onset sarcoidosis*.¹⁷⁸ So far 13 disease-causing mutations in the *NOD2* gene have been reported to result in PGA.¹³

Like *NLRP3*, *NOD2* (nucleotide-binding oligomerization domain protein 2) is a member of the NOD-like receptor family (NLR), playing an important role in innate immune defenses through detection and clearance of intracellular invasive bacteria and viruses.¹⁷⁹ It encodes a protein, *NOD2*, that has the typical three-domain protein structure of an NLR member: a caspase recruitment domain (CARD), a NACHT domain, and a leucine-rich repeat domain.¹⁸⁰ *NOD2* is present in the cytoplasm in an autoinhibited conformation, and its activation by interaction with pathogen-associated molecular patterns leads to its oligomerization via the NACHT domain and to exposure of the CARD.¹⁸¹ CARD-CARD interaction induces the recruitment of the serine-threonine kinase RICK, which results in activation of NF- κ B.^{182,183} Translocation of NF- κ B to the nucleus initiates the activation of several inflammatory genes. Gain-of-function mutations in the NACHT domain of *NOD2* might decrease the threshold for the spontaneous oligomerization of this protein, leading to a constitutive activation of NF- κ B and the inflammatory manifestations observed in PGA (see Fig. 165.1b).^{184,185}

Clinical features

PGA symptoms typically occur before the age of 4 years due to a granulomatous inflammation of eyes, joints, and skin that leads to an early-onset classic triad of disease manifestations consisting of chronic uveitis, arthritis, and dermatitis.¹⁷⁶ All patients have chronic arthritis, which almost always presents as polyarthritis (96% of cases).¹⁷⁶ A symmetric hypertrophic tenosynovitis is observed in approximately 40% of patients.¹⁷⁶ Ocular involvement is very frequent (84%) and is usually chronic and persistent (Fig. 165.8a).^{176,186} Uveitis manifests more commonly as panuveitis (50%), but 25% of the subjects may have anterior uveitis.^{176,186} Most of the patients have bilateral eye involvement, and cataract and glaucoma occur in 50% and 30%, respectively, of these individuals.^{176,179} Up to 40% of untreated patients with

Fig. 165.8 (a) Diffuse ichthyosis-like skin rash in a patient with Blau syndrome. (b) Cataract and anterior synechiae occurring as sequelae of chronic anterior uveitis in a patient with Blau syndrome.

PGA uveitis develop irreversible blindness.¹⁸⁶ Typical PGA exanthema is described as ichthyosis-like and occurs in over 85% of patients (see Fig. 165.8b).^{178,179} Less commonly observed findings include fever, camptodactyly, and central neuropathy.¹⁷⁸

Laboratory findings

Laboratory studies demonstrate persistent leukocytosis, thrombocytosis, and increased ESR and CRP levels.¹⁷⁶ Synovial, skin, and liver biopsy specimens may show noncaseating granulomas, but a definitive diagnosis is achieved only with DNA sequencing showing *NOD2/CARD15* mutations.^{13,186}

Complications of untreated disease

The most significant morbidity is eye involvement, and cataract, glaucoma, and retinal detachment are frequent complications and may lead to visual impairment and permanent vision loss.^{176,187} Untreated patients may also develop complication of chronic arthritis, such as joint deformities, ankylosis, and contractures of small joints, and decreased motion of large joints.^{188,189}

Treatment

Optimal therapy for PGA has not been well defined. NSAIDs can be used for mild clinical manifestations, whereas severe symptoms are treated with systemic corticosteroids.¹⁹⁰ Immunosuppressants (methotrexate and cyclosporine) and biologics targeting TNF and IL-1 (etanercept, infliximab, and anakinra) have been reported to result in clinical benefit, especially in patients with refractory uveitis.^{179,186}

PYOGENIC STERILE ARTHRITIS, PYODERMA GANGRENOSUM, AND ACNE (PAPA) SYNDROME

Background

In 1997 Lindor and colleagues¹⁹¹ described a kindred of 10 affected members with pyogenic arthritis, pyoderma gangrenosum and severe cystic acne. A second kindred of 11 affected patients was described by Wise and associates in 2000¹⁹²; in 2002, using genome-wide linkage, *CD2BP1/PSTPIP1* was identified, with two missense mutations, A230T and E250Q, as the disease-causing gene in both kindreds.¹⁹³

Genetics and pathophysiology

Pyogenic sterile arthritis, pyoderma gangrenosum, and acne (PAPA) syndrome (OMIM #604416) is a pyogenic autoinflammatory disease caused by autosomal dominant mutations in the *PSTPIP1* gene, also called *CD2BP1*.¹⁹³ Fourteen variants have been described in *PSTPIP1*, with four of them so far determined to be disease related.¹³ PAPA is exceedingly rare, and fewer than 10 families with the syndrome have been identified so far.

PSTPIP1 encodes a cytoskeletal protein, proline/serine/threonine phosphatase-interacting protein (*PSTPIP1*). *PSTPIP1* is an adaptor protein that interacts with the protein tyrosine phosphatases (PEST type), Wiskott-Aldrich syndrome protein, and pyrin, the protein encoded by *MEFV*, the gene mutated in FMF.¹⁹⁴⁻¹⁹⁶ Disease causing *PSTPIP1* mutations diminish the interactions with PEST-type protein, which results in increased phosphorylation of mutated *PSTPIP1* and increased interaction with pyrin.¹⁹⁶ It is suggested that *PSTPIP1* mutations increase activation of the pyrin (pyroptosome) associated IL-1 β activation¹⁹⁷; however, *PSTPIP1* does not seem to be an essential regulator of the Nlrp3, Aim2, or Nlrp4 IL-1 β -activating inflammasomes in a mouse model.¹⁹⁸

Clinical features

Fever is rarely observed in PAPA patients, who instead have early-onset flares of painful sterile and deforming arthritis (Fig. 165.9a), cutaneous ulcers (pyoderma gangrenosum; see Fig. 165.9b), and pathergy, cystic acne, or skin abscesses at the injections sites.^{193,199,200} PAPA syndrome symptoms usually persist into adulthood, and significant joint destruction with an impaired quality of life related to physical disability is observed.²⁰¹ A recent report describing five PAPA syndrome patients noted that three patients had an A230T mutation, one had an E250Q mutation, and one had the novel E250K mutation. All patients had sterile arthritis and pyoderma gangrenosum, three patients had sterile skin abscesses, and two had cystic acne. Other clinical findings were one osteomyelitis episode in one patient, recurrent otitis in two patients, and lymphadenopathy, splenomegaly, thrombocytopenia, hemolytic anemia, pharyngeal papillomatosis, and T-cell large granular lymphocytosis in one patient.²⁰¹ More typically around puberty, cystic acne and hidradenitis suppurativa of the axilla and groin can develop.^{191,202}

Laboratory findings

Laboratory findings are nonspecific and include leukocytosis and increased ESR and CRP levels during flares.^{193,199} Joint aspirates are aseptic and the predominant cells in the synovial fluid aspirate and in skin biopsy specimens are mature neutrophils.

Complications of untreated disease

Pyogenic arthritis results in joint destruction, with ankylosis affecting joint mobility. The pyoderma lesions heal with significant scarring of the skin.

Fig. 165.9 (a) Magnetic resonance image of the right elbow showing synovial thickening and enhancement with moderate fluid in a patient with PAPA syndrome (pyogenic sterile arthritis, pyoderma gangrenosum, and acne). (b) Extensive pyoderma gangrenosum lesion in a patient with PAPA syndrome. (c) Diffuse erythematous and scaly skin rash in a patient with *CARD14*-mediated psoriasis.

Treatment

Treatment of PAPA syndrome is challenging, and corticosteroids, thalidomide, cyclosporine, dapsone, tacrolimus, and intravenous immunoglobulin have been used with variable individual responses.^{201,203} Regarding biologics, two case reports showed that etanercept was efficacious in PAPA syndrome treatment.^{203,204} Responses were observed to infliximab in one patient, to adalimumab in two patients, and to anakinra in one patient.²⁰¹ On the other hand, two patients did not respond to anakinra, one did not respond to infliximab, and another did not respond to etanercept therapy.²⁰¹ In general, monoclonal anti-TNF antibodies (infliximab and adalimumab) were considered more effective in treating skin manifestations of PAPA syndrome.²⁰¹

MAJEED SYNDROME

Background

Majeed syndrome was first reported in 1989, and the original report described three members of a consanguineous Arab family who had chronic recurrent multifocal osteomyelitis, congenital dyserythropoietic anemia, and neutrophilic dermatosis.²⁰⁵ In subsequent reports the same investigators described a fourth child with the disease born into the first family and a second Arab family with two affected siblings born to consanguineous parents.^{206,207} In 2005 Ferguson and colleagues²⁰⁸ identified the genetic cause of the disease through homozygosity mapping and parametric linkage analysis of six affected members of the two previously reported families.

Genetics and pathophysiology

Majeed syndrome (OMIM #146462) is a pyogenic autoinflammatory disease caused by autosomal recessive loss-of-function mutations in the *LPIN2* gene encoding the protein lipin-2.^{6,208,209} Twelve mutations have so far been described in *LPIN2*, and four of them are disease causing.⁶ Although the pathogenesis of the disease is unclear, the recently reported clinical responses to IL-1 inhibition in two patients with Majeed syndrome suggest that the resulting mechanism may be IL-1 mediated.²¹⁰

Clinical features and laboratory findings

Majeed syndrome is clinically characterized by neonatal-onset recurrent multifocal osteomyelitis, neutrophilic dermatosis, and congenital dyserythropoietic anemia.²¹¹ Disease flares occur one to three times per month and are sometimes associated with mild fever. The patients failed to thrive with height and weight below the 5th percentile and with delayed bone age. All patients reported had significant hepatosplenomegaly and required blood transfusions on several occasions.²⁰⁵ Pustular dermatitis is the most common skin manifestation, although psoriasis-like lesions have also been reported.²¹¹ The most frequent sites of osteomyelitis are the clavicles, sternum, and long bones, whereas the mandible and vertebral bodies are rarely affected.^{206,209} Bone biopsy studies usually show a neutrophilic infiltrate.^{206,208}

Treatment

Majeed syndrome is unresponsive to treatment with antibiotics and may respond to NSAIDs, corticosteroids, IFN- γ bisphosphonates, and anti-TNF drugs.^{208,209,211} Recently the efficacy of IL-1 inhibition with either anakinra or canakinumab was demonstrated in two brothers with Majeed syndrome who showed no response to anti-TNF therapy.²¹⁰

FAMILIAL COLD AUTOINFLAMMATORY SYNDROME 2

Background

In 2008 two unrelated families from Guadeloupe who experienced episodes of fever, arthralgia, and myalgia after generalized exposure to cold were found to have autosomal dominant mutations in *NLRP12*.²¹² The disorder is referred to as an *NLRP12-associated disease* (*NLRP12AD*) and is also known as *familial cold autoinflammatory syndrome 2* (*FCAS2*) since it clinically resembles FCAS, an *NLRP3*-associated cryopyrinopathy. Several more cases and families have been described.²¹²⁻²¹⁴ The effects of the disease-causing mutations on *NLRP12* function are currently being investigated.

Genetics and pathophysiology

Autosomal dominant mutations in *NLRP12*, also known as *NALP12* and *MONARCH-1*,²¹² cause this rare disease, which can be familial but in most instances presents as sporadic disease. *NLRP12* is a member of the NLR family of intracellular sensors of molecular danger signals, but the disease pathogenesis remains unclear. Some data suggest that *NLRP12* acts as a proinflammatory protein on caspase-1 signaling and speck formation with the adaptor protein ASC.²¹⁵ Monocytes from patients with mutated *NLRP12* have increased concentrations of ROS and up regulation of antioxidant systems in the absence of stimulation by pathogen-associated molecular patterns²¹⁴ and accelerated kinetics of IL-1 β secretion.¹⁴⁰ The early secretion of IL-1 β , even in the absence of an overall increased secretion of the cytokine, may be sufficient to account for the mild inflammatory symptoms seen in this syndrome.

Clinical features and laboratory findings

In the nine patients with FCAS2 described so far, the age of onset of the clinical manifestations varied from the first days of life to 20 years of age.²¹²⁻²¹⁴ Patients with FCAS2 experience cold-induced episodes of high-grade fever and urticarial rash associated with myalgia, arthralgia, abdominal pain, and headache.²¹²⁻²¹⁴ Other manifestations observed are vomiting, oral ulcers, and lymphadenopathy.²¹²⁻²¹⁴ Two of the nine patients described, the only two monozygotic twins, had sensorineural bilateral hearing loss.²¹² In the nine patients, the length of episodes varied from several hours to 15 days.²¹²⁻²¹⁴

During flares, FCAS2 patients can have an increase in acute-phase reactants (ESR and CRP level).²¹²⁻²¹⁴ However, three of the nine patients described

did not show evidence of increased levels of inflammatory serum markers.²¹²⁻²¹⁴

Treatment

Preventing cold exposure can avoid or ameliorate FCAS2 symptoms.²¹²⁻²¹⁴ Symptoms can be partially controlled with NSAIDs and variable courses of oral steroids.²¹²⁻²¹⁴ Prophylactic administration of low-dose steroids and antihistamines during winter prevented disease manifestations in one patient.²¹⁴ Colchicine was not effective in the three patients reported to have received it.^{212,213} In the two patients who received anakinra, although an initial partial clinical response was observed, the drug was discontinued after 14 months due to a progressive clinical relapse.²¹⁵

PROTEASOME-ASSOCIATED AUTOINFLAMMATORY SYNDROMES

Background

In 1993 Tanaka and colleagues²¹⁶ reported on 2 Japanese patients with lipodystrophy, muscle atrophy, and skin eruptions; they proposed that 13 Japanese patients previously described had the same syndrome, including those in reports dating back to 1939 describing 96 patients with lipodystrophy, rashes, and systemic inflammation. In 2010 Garg and coworkers²¹⁷ reported on two Mexican siblings and a Portuguese patient with an autosomal recessive syndrome and noted the similarities with the Japanese patients; they termed the disorder *JMP syndrome*, for joint contractures, muscular atrophy, microcytic anemia, and panniculitis-induced lipodystrophy. All patients had short stature, generalized lipodystrophy, and severe joint contractures of the elbows, hands, fingers, feet, and toes. In childhood, all patients had erythematous nodular skin lesions, and one patient had panniculitis on skin biopsy. Earlier in the same year, Torreló and colleagues²¹⁸ proposed the acronym *CANDLE* (chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature) for a syndrome described in four patients, including two sisters, who had recurrent fevers, annular erythematous skin lesions, lipodystrophy, and high levels of acute-phase reactants with hypochromic anemia.

Genetics and pathophysiology

In 2011 several studies showed that autosomal recessive mutations in the proteasome subunit β type 8 (*PSMB8*) gene cause JMP syndrome,²¹⁹ Nakajo-Nishimura syndrome (NNS),²²⁰ Japanese autoinflammatory syndrome with lipodystrophy,²²¹ and *CANDLE* syndrome²²² (OMIM #256040), which indicates that these disorders are disease phenotypes along the same disease spectrum.^{218,222,223} Currently, three mutations in *PSMB8* have been described (T75M, C135X, and G201V).

Proteasomes are protein degradation systems that target intracellular polyubiquitinated proteins derived from self-structures or foreign structures for proteolytic destruction.²²⁴ Proteasomes are implicated in cellular processes including apoptosis, the removal of various misfolded and immature proteins, and the production of peptides for presentation by major histocompatibility complex class I molecules (Fig. 165.10).²²⁵ In response to cytokines, the expression of three alternative catalytic subunits designated as β 1i/LMP2/*PSMB9*, β 2i/Mec11/*PSMB10*, and β 5i/LMP7/*PSMB8* is induced resulting in the formation of a proteasome isoform known as the *immuno-proteasome* (I-proteasome). I-proteasome expression is inducible in most tissues, but it is constitutively expressed in hematopoietic cells, especially lymphocytes and monocytes.²²⁶ In patients who are homozygous for *PSMB8* mutations, the assembly of the I-proteasome complex is defective,²¹⁹⁻²²¹ and polyubiquitinated proteins accumulate in tissues in these patients. Gene expression profiling using whole-blood microarray identified the IFN pathway as the most differentially regulated pathway in all six *CANDLE* syndrome patients tested,²²² and inhibition of IFN signaling with the Janus kinase (JAK) inhibitor tofacitinib decreased IFN- γ -induced IP-10 production by the patients' cells.²²² This suggested that the IFN pathway may be a target for therapeutic intervention.

Clinical features and laboratory findings

Recently, 28 patients with NNS were compared with 3 patients with JMP syndrome and 9 with *CANDLE* syndrome, and the clinical disease spectrum of the proteasome-associated autoinflammatory syndromes is summarized here. Common clinical features seen in the majority of the patients historically described as having either NNS, JMP syndrome, or *CANDLE* syndrome

Fig. 165.10 Fibroblasts from *PSMB8* knockout mice, when stimulated with interferon (IFN), accumulate increased amounts of oxidant-damaged defective ribosomal products (DRiPs) that cannot be degraded and form aggregates leading to cell stress and apoptosis.

include high fevers; clubbed fingers; skin rashes, varying from small nodules to violaceous plaques (Fig. 165.11a), also described as “pernio-like” lesions, covering the trunk and extremities, and facial rashes leading to various degrees of edema and mimicking heliotrope rashes in some patients; arthritis with more variable joint contractures; and progressive lipodystrophy that initially affects the face and extremities but can be generalized (see Fig. 165.11b). Clubbed fingers are a result of the arthropathy and the lipoatrophy that develops early in the hands, but the elevation of the nail bed noted in hypertrophic osteoarthropathy is not typically seen in these patients. Myositis (see Fig. 165.11c), hepatosplenomegaly, basal ganglia calcification (see Fig. 165.11d), microcytic anemia, and increased acute-phase reactants (ESR and CRP level) are also observed in these patients. More variable symptoms include muscle atrophy, dyspnea, seizures, lymphadenopathy, low weight and height, hepatosplenomegaly, and metabolic abnormalities, including truncal obesity and hyperlipidemias, insulin resistance, and acanthosis nigricans.^{217,222,227} Clinical and laboratory findings less frequently observed are perioral swelling, parotitis, conjunctivitis or episcleritis, hypertrichosis, ear and nose chondritis, lymphocytic aseptic meningitis, recurrent otitis or sinusitis, epididymitis, thrombocytosis, hypergammaglobulinemia, neutropenia, and thrombocytopenia.^{220,221}

Complications of untreated disease

In childhood severe inflammatory attacks that cannot be controlled by any antiinflammatory medications including high-dose steroids can result in sudden death, likely from a triggered systemic inflammatory syndrome resulting in organ failure. Some insights into the development of organ damage from untreated disease in older patients are provided by earlier reports on adult patients^{217,227} that suggested the development of muscle atrophy and joint contracture, cardiac arrhythmias, and heart failure. Autopsy results from a patient who died of heart failure have provided further insights into the pathologic features of the disease. Extensive endothelial cell damage and calcification of multiple vessels, including cardiac and basal ganglia vessels, was observed, and it was proposed that ischemia may cause the severe skeletal muscle atrophy and myofibrillary necrosis. Other muscles affected were the tongue, extraocular muscles, and heart.²²⁸

Treatment

In the nine patients previously mentioned, most clinical symptoms partially responded to high doses of steroids (1 to 2 mg/kg/day).²²² NSAIDs, colchicine, dapsone, methotrexate, tacrolimus, and azathioprine were not effective in most patients.²²² A variable response was observed to anti-TNF, anti-IL-1, and anti-IL-6 agents, but complete disease remission was not achieved with any of the therapies described.²²² Additionally, lipodystrophy progressed in all patients despite immunosuppressive and cytokine-targeted therapy.²²² The increase in STAT1 phosphorylation and the strong IFN response suggest that IFN signaling may be a therapeutic strategy for the treatment of

Fig. 165.11 (a) Erythematous, annular, and nodular rash in a patient with CANDLE syndrome (chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature). (b) Lipodystrophy (black arrows) and acanthosis nigricans (red arrow) in a patient with CANDLE syndrome. (c) Bilateral thigh magnetic resonance image (MRI) showing signs of myositis (white patches) in a patient with CANDLE syndrome. (d) Brain MRI showing basal ganglia calcifications in a patient with CANDLE syndrome.

CANDLE syndrome and other proteasome-associated autoinflammatory syndromes.

SYNDROMES PRESENTING WITH PREDOMINANTLY SKIN INVOLVEMENT

Deficiency of interleukin 36 receptor antagonist

Genetics and pathophysiology

Recently 16 family members of nine Tunisian families with generalized pustular psoriasis and fever flares were found to be homozygous for a mutation in the *IL36RN* gene, L27P, which indicates a founder mutation in Tunisia leading to this disease.²²⁹ Most of the patients described (75%) developed the disease during childhood (7 days to 11 years of age).²²⁹ Additionally, three unrelated English patients with a similar phenotype had mutations in *IL36RN*.²³⁰ More recently, 2 out of 14 Japanese patients with pustular psoriasis were found to be compound heterozygous for a splice-site mutation resulted in the skipping of exon 3; in addition, a missense mutation leading to expression of a nonfunctional protein was found in one of the patients, and a nonsense mutation leading to a stop codon R10X was found in the other.²³¹

IL36RN encodes for the IL-36 receptor antagonist (IL-36Ra), which binds to the IL-36 receptor and thus blocks binding by IL-36 α , IL-36 β , and

IL-36 γ and inhibits NF- κ B and MAPK signaling.²²⁹ IL-36Ra is highly expressed in keratinocytes and plays an important role in down regulating exacerbated inflammatory responses. Therefore the absence of IL-36Ra in patients with the described *IL36RN* mutations leads to constitutively enhanced IL-36 receptor signaling.

Clinical features and laboratory findings

Patients have recurrent and sudden onset of skin flares characterized by generalized erythematous and pustular skin rashes, associated with high fevers up to 40 to 42°C, asthenia, high levels of acute-phase reactants (e.g., CRP), and high white blood cell counts.^{229,230} Secondary skin infections and sepsis may also occur.²²⁹ In most patients, the disease flares are thought to be triggered by viral or bacterial infections (14 of 16 patients), but withdrawal of retinoid therapy, menstruation (6 patients), and pregnancy have also been triggers.^{229,230} Skin biopsy specimens demonstrate spongiform pustules, acanthosis and parakeratosis in the stratum corneum, and infiltration of the skin by CD8+ and CD3+ T cells and macrophages.²²⁹ Because the *IL36RN* mutations described result in a decrease or absence of IL-36Ra, the resulting disease was proposed to be called *deficiency of IL-36 receptor antagonist* (DITRA; OMIM #614204).²²⁹

Treatment

The definitive treatment for DITRA has not yet been established. Acitretin was used as treatment for 12 of the 19 patients described so far.^{229,230} Other

therapeutic regimens tried with variable individual responses were oral steroids in four patients, methotrexate in three patients, cyclosporine in three patients, adalimumab in two patients, infliximab in two, and etanercept in one.^{229,230} Topical steroids were used in three patients.²²⁹

CARD14-mediated psoriasis

Background

In 1994 Tomfohrde and colleagues²³² identified a psoriasis susceptibility locus, PSORS2, in a single large family of European ancestry that mapped to human chromosomal region 17q25-qter. Affected members had plaque psoriasis, and approximately 30% had psoriatic arthritis. A five-generation psoriasis pedigree from Taiwan exhibited significant linkage to the same locus.²³³ Recently, targeted and exome capture followed by next-generation sequencing of DNA obtained from members of the family identified a splice-site mutation in the caspase recruitment domain-containing protein 14 gene (*CARD14*) encoding a protein that carries a CARD mediating the assembly of CARD-containing proteins into apoptosis- and NF- κ B-signaling complexes.²³⁴

Genetics and pathophysiology

Autosomal dominant gain-of-function mutations in the *CARD14* gene caused plaque psoriasis in two families and severe generalized pustular psoriasis in an unrelated child who had a sporadic *de novo* mutation in *CARD14*.²³⁵ Mutations in *CARD14* were also shown to cause familial pityriasis rubra pilaris in 15 family members of three kindreds.²³⁶ In addition to the three mutations associated with familial disease, additional rare variants were found in several probands from large psoriasis cohorts. Although the contribution of those variants to psoriasis is not fully understood, some of these mutations were NF- κ B activating and likely constitute rare variants with a large effect size, which suggests the possibility of development of sporadic disease such as that seen in the child with a *de novo* mutation mentioned earlier.^{235,237} The fact that *CARD14* mutations cause familial psoriasis as well as pityriasis rubra pilaris indicates that these disorders fall along the same disease spectrum.

Clinical features and laboratory findings

Patients with *CARD14* mutations can have typical plaque psoriasis of variable severity that can be mostly limited to certain areas of the skin or can be generalized and involve 100% of the body surface area (see Fig. 165.9c).^{235,236} Fever and other systemic manifestations are generally not present but can occur with superinfection of the skin in patients with *CARD14*-mediated psoriasis (CAMPS; OMIM #602723).^{235,237}

Treatment

The therapeutic approach in CAMPS includes drugs used for the treatment of moderate to severe psoriasis, such as methotrexate, cyclosporine, anti-TNF agents, and, more recently, biologics targeting IL-17 and IL-23.²³⁸⁻²⁴⁰ Familial pityriasis rubra pilaris is considered refractory to the standard therapies, and a partial response to retinoids, cyclosporine, and etanercept has been described.^{236,241}

SYNDROMES PRESENTING WITH INFLAMMATORY BOWEL DISEASE

Background

In 2009 Glocker and colleagues²⁴² mapped chromosome arms 11q and 21q as the regions of interest in two families with early-onset severe enterocolitis. Targeted sequencing showed a homozygous missense mutation in *IL10RA* and a homozygous nonsense mutation in *IL10RB* in each of the families evaluated. In 2010, the same group found that autosomal recessive mutations in the *IL10* gene can also cause refractory early-onset inflammatory bowel disease (EO-IBD).²⁴³

Genetics and pathophysiology

Infantile IBD is caused by autosomal recessive mutations in the genes encoding the IL-10 receptor (OMIM #613148, OMIM #612567) and IL-10 (OMIM #612381).^{242,243} In total, six disease-causing mutations in each of the IL-10

receptor genes (*IL10RA* and *IL10RB*) and two mutations in the *IL10* gene have been described.

IL-10 is an antiinflammatory cytokine that is secreted by a wide variety of cells and has immunoregulatory effects on T cells, B cells, myeloid cells, and other cell types. IL-10 limits the secretion of proinflammatory cytokines such as TNF- α and IL-12. IL-10 signals through the IL-10 receptor, which consists of two receptor subunits, IL-10RA and IL-10RB. Dysfunction of IL-10 receptor and impaired signaling of IL-10 leads to increased production of proinflammatory cytokines, including TNF- α , IL-1 α , IL-1 β , IL-2, and IL-6, and chemokines, including RANTES, MIP-1 α , and MIP-1 β . Mice deficient in either IL-10RA or IL-10RB also have severe enterocolitis.^{242,243}

Clinical features and laboratory findings

Patients with EO-IBD have severe enterocolitis characterized by bloody diarrhea, colonic abscesses, perianal fistula, and oral ulcers.^{242,244} Symptoms usually start in the first year of life, before 3 months of age.²⁴⁴ Additionally, they have impaired weight and height development and recurrent fever.²⁴⁴ Musculoskeletal manifestations include acute recurrent arthritis of large joints, especially the knees.²⁴⁴ Remarkably, recurrent folliculitis has been observed in 75% of patients.²⁴⁴ Recurrent infections, such as otitis media, bronchitis, pneumonia, septic arthritis, and renal abscesses, may indicate a defect in the immune responses in patients with EO-IBD.^{242,244}

Treatment

Because EO-IBD is a severe disease and is frequently refractory to standard immunosuppressant therapy, hematopoietic stem cell transplantation (HSCT) has been proposed as a curative treatment.²⁴⁵ HSCT was performed in 9 of the 29 patients with IL-10 deficiency described, and complete clinical remission was achieved in all but one of these patients.²⁴⁴⁻²⁴⁶

SYNDROMES PRESENTING WITH AUTOINFLAMMATION AND IMMUNODEFICIENCY

The description of additional monogenic diseases has led to the identification of conditions that present with autoinflammatory phenotypes but also with features of immunodeficiencies. The mixed phenotype is determined by the impact the mutation can have in different immune cells. Immunodeficiencies have also been suggested to be present in patients with HIDS and EO-IBD. Two conditions have been described recently that are caused by autosomal dominant mutations in *PLCG2*: PLC γ 2-associated antibody deficiency and immune dysregulation (PLAID) and autoinflammation and PLC γ 2-associated antibody deficiency and immune dysregulation (APLAID).^{247,248} Another condition is caused by autosomal recessive mutations in *HOIL*, a component of the linear ubiquitin chain assembly complex (LUBAC).²⁴⁹ These mutations result in impairment of LUBAC stability, which leads to reduced NF- κ B activation in response to IL-1 β in fibroblasts but hyperresponsiveness to IL-1 in mononuclear leukocytes, particularly monocytes.²⁴⁹ PLAID is characterized by cold-induced urticaria, autoimmune manifestations, and susceptibility to infections, whereas APLAID leads to early-onset recurrent erythematous plaques and vesicopustular skin lesions associated with arthralgia, corneal erosions, and interstitial pneumonia.²⁴⁸ The two patients identified with APLAID so far have developed recurrent sinopulmonary infections, presumably due to a lack of class-switched memory B cells.²⁴⁸ Both patients described showed partial responses to anakinra and to high-dose corticosteroids.²⁴⁸

Of the three patients with *HOIL* deficiency who have been described, two were siblings born to non-consanguineous parents.²⁴⁹ All three patients had early-onset recurrent fevers, hepatosplenomegaly, and increased levels of acute-phase reactants.²⁴⁹ Two patients had chronic bloody diarrhea and two had eczema and diffuse erythroderma. These patients experienced severe recurrent pyogenic, fungal, and viral infections, and all three patients had a fatal outcome.²⁴⁹ In addition, all three patients had cardiomyopathy, and two patients had amylopectinosis in cardiomyocytes.²⁴⁹ The autoinflammatory manifestations in two of the three patients were partially responsive to corticosteroids but refractory to colchicine, anti-TNF agents, and anti-IL-1 agents. The third patient underwent allogeneic HSCT at the age of 13 months but died 3 years after transplantation.²⁴⁹

Sarcoidosis

■ STERLING G. WEST

- Sarcoidosis is a systemic inflammatory disorder of unknown cause characterized by noncaseating, granulomatous inflammation that can affect virtually any organ.
- Acute and chronic forms of inflammatory arthritis particularly involve the ankles and knees.
- Cystic bone lesions may produce dactylitis or rarely involve the skull, vertebrae, ribs, or pelvis.
- Muscle involvement is usually asymptomatic but may cause acute or chronic myopathies or nodular masses.
- Nonmusculoskeletal features are common and include bilateral hilar adenopathy, pulmonary infiltrates, uveitis, cardiac and neurologic involvement, and skin lesions such as erythema nodosum and lupus pernio.

HISTORY

Sarcoidosis derives from the Greek *sarco*, meaning “flesh,” *eidos*, meaning “like,” and *osis*, meaning “condition.”¹ In 1877, Jonathan Hutchinson described the first case at King’s College Hospital in London. Later, Caesar Boeck advanced the description of sarcoidosis by emphasizing the granulomatous inflammation characteristic of this disease. He was the first to use the term *sarkoid* (sarcoid) because he thought the lesions resembled sarcoma but were benign. In 1953, Sven Löfgren described the acute sarcoidosis syndrome of bilateral hilar adenopathy and erythema nodosum, frequently associated with arthritis, fever, and uveitis. Over the past century, sarcoidosis has become recognized as a multisystem granulomatous disorder with protean manifestations that may affect any organ.^{2,3}

EPIDEMIOLOGY

Sarcoidosis occurs worldwide.⁴ It has been reported in all races and ethnic groups, but with marked variations. Prevalence estimates using mass chest radiographic screening range from 0.2 in 100,000 (Portugal) to 64 in 100,000 (Sweden). In the United States the age-adjusted annual incidence rates are three times higher for blacks (35.5 in 100,000) than for whites (10.9 in 100,000) with a lifetime risk of sarcoidosis for U.S. blacks of 2.4% and for U.S. whites of 0.85%. In most series sarcoidosis affects females slightly more than males (57% to 64% females). People of all ages can be affected, but it particularly occurs in young adults 20 to 40 years of age (over 70% of cases) with possibly a second peak in women in the seventh decade.

Clinical evidence indicates that the presentation and severity of sarcoidosis vary according to race and ethnicity. Whites are more likely to have erythema nodosum, have less extrapulmonary involvement, and have lower age-adjusted mortality than other racial groups. The Japanese have more cardiac and ocular involvement, and blacks have the most severe disease with higher mortality rates.

CLINICAL FEATURES

Sarcoidosis is a systemic inflammatory disorder. The clinical manifestations are diverse, ranging from abnormal chest radiographic findings in an asymptomatic individual (up to 50% of patients) to severe multiorgan

involvement.^{2,3} Because there is no specific test for sarcoidosis, the diagnosis is established when well-recognized clinical and radiographic findings are supported by histologic evidence of widespread noncaseating epithelioid granulomas in more than one organ system.⁵ Other granulomatous diseases must be excluded. The presenting manifestations and cumulative organ involvement in sarcoidosis patients are shown in Table 166.1. Recently the ACCESS (A Case Control Etiologic Study of Sarcoidosis) trial evaluating 736 sarcoidosis patients confirmed that 95% of patients had thoracic involvement, 50% had extrathoracic involvement, and only 2% had isolated extrathoracic sarcoidosis. Notably, there were significant differences in clinical findings and prognosis among groups on the basis of race, sex, and age.⁶

Respiratory tract involvement

Respiratory tract involvement is the most common visceral manifestation (95% of cases), and any part from sinuses (2% to 18%) to lungs can be involved.^{3,7} The clinical spectrum ranges from asymptomatic hilar adenopathy (50% to 60%) to an interstitial lung disease with alveolitis. Pleural effusions are rare (fewer than 5% of cases). Endobronchial involvement is found on biopsy in 50% and may lead to airway stenosis (10%) and wheezing. Symptoms of lung disease include dry cough (30%), dyspnea (28%), and chest pain (15%). Hemoptysis is rare and occurs primarily in patients with fibrosis and cavitation filled with aspergillomas. Lung crackles are heard in only 20%, and clubbing is rare. Pulmonary hypertension occurs in 5% to 15% of all patients and in 50% of patients with dyspnea.

Chest radiographs show abnormal findings in 90% of patients and are classified using the modified Scadding staging system: stage 0, normal; stage I, bilateral hilar adenopathy; stage II, adenopathy with pulmonary infiltrates; stage III, pulmonary infiltrates only; and stage IV end-stage pulmonary fibrosis (Fig. 166.1). Notably, the stages are not chronologic and do not indicate disease chronicity or correlate with changes in pulmonary function. Hilar adenopathy is noted in 50% to 85% of patients. In the majority of patients hilar node enlargement is bilateral, but unilateral hilar (usually right-sided) and/or unilateral paratracheal adenopathy is present in up to 4% of patients. Parenchymal changes occur in 25% to 60% of cases, have a mid- to upper-zone predominance, and typically are located along the bronchovascular bundle. High-resolution computed tomography (HRCT) is more sensitive than the chest radiography and may show mediastinal node involvement and/or unexpected parenchymal disease in patients with normal chest radiographic findings. Up to 70% of patients with abnormal findings on chest radiographs have airflow abnormalities at presentation. Pulmonary function tests (PFTs) typically show a restrictive pattern, with a reduction in vital capacity, residual volume, and total lung capacity.^{3,7} The loss of diffusing capacity is the most common abnormality. Obstructive airway disease also occurs in 50% of patients due to obstruction of large and small airways from endobronchial granulomas or bronchiolitis and is a poor prognostic sign, suggesting extensive and progressive disease.

The characteristic bronchoalveolar lavage fluid cell differential shows greater than 30% to 60% lymphocytes. A CD4/CD8 T-cell ratio greater than 3.5 (94% specific, 52% sensitive) is supportive of a diagnosis of sarcoidosis. The CD4+ T cells are activated with an effector memory phenotype (CD45RO). Notably, the number of cells exhibiting cytotoxic activity (CD8+ T cells, natural killer [NK] cells, and NK T cells) increases progressively between Scadding stages I and IV. An adequate transbronchial biopsy consists of six specimens from the upper and lower lobes. With abnormal chest radiographic findings the diagnostic yield is over 90%. Endobronchial ultrasonography with transbronchial needle aspiration of hilar/mediastinal adenopathic lesions has a diagnostic yield of 83%.

Patients with good prognostic signs (Scadding stage 0 and I; Löfgren syndrome; asymptomatic stage II and III disease) should be observed for 3

TABLE 166.1
Clinical features of sarcoidosis

Manifestation	Presenting (%)	Cumulative (%)
Respiratory tract	25-50	95
Constitutional	25	33-70
Adenopathy	10-20	40
Joint disease	1-14	4-38
Uveitis	5	10-20
Hepatosplenomegaly	4	5-20*
Cutaneous	3	15-30
Other	4	
Heart	<1	5-10*
Neurologic	<1	5-10
Muscle	<1	1-5*
Bone	<1	1-13

*At autopsy, 20%-67% have heart involvement; on biopsy, 50%-80% have muscle and liver involvement.

Fig. 166.1 Pulmonary sarcoidosis. Chest radiograph demonstrating bilateral hilar adenopathy.

to 6 months before starting therapy. During the first 2 to 3 years, repeat chest radiographs and pulmonary function tests should be performed every 3 to 6 months in patients with symptoms and/or radiographic abnormalities to monitor for progression. For the 10% to 30% of patients who develop symptomatic and progressive stage II and III lung disease (a decrease in total lung capacity of 10% or more, a decrease in forced vital capacity of 15% or more, a 20% or greater decrease in lung diffusion of carbon monoxide, or progressive radiographic changes) current guidelines suggest the use of 40 to 60 mg (1 mg/kg/day) of prednisone daily for 8 to 12 weeks, with a gradual tapering of the dose to 30 mg every other day by 6 months, 20 mg every other day by 9 months, and 10 mg every other day by 12 months. Corticosteroid therapy often lasts for 2 years or longer. More than 70% of patients respond favorably, but relapses occur in 25% to 50% after tapering or discontinuation of corticosteroids, so patients need to be monitored closely. Some patients need 10 to 20 mg every other day indefinitely to prevent relapses. Steroid-sparing agents include methotrexate (15 mg/wk), mycophenolate mofetil (1 to 1.5 g twice daily), azathioprine (2 mg/kg/day), leflunomide (10 to 20 mg/day), and/or anti-tumor necrosis factor (anti-TNF) biologics (infliximab 3 to 5 mg/kg every 1 to 2 months intravenously). Pulmonary hypertension may respond to sildenafil, bosentan, or epoprostenol. In patients in whom therapy fails and who develop end-stage pulmonary fibrotic disease, lung transplantation offers a potential cure, although

Fig. 166.2 Lupus pernio. Violaceous nodular and plaquelike eruptions on the nose, cheeks, and forehead in a patient with chronic sarcoidosis.

asymptomatic recurrence of sarcoidosis in the allograft has been observed in 50%.

Ophthalmologic involvement

Eye involvement occurs in 25% to 50% of patients and can be the major clinical manifestation.⁸ It can be the initial manifestation (5% of cases) or occur at any time during the disease course. Because the disease may be asymptomatic (33%), all patients with sarcoidosis should have a baseline slit-lamp and fundusoscopic eye examination with repeat examinations annually or with development of symptoms. Any area of the eye may be involved. Acute anterior uveitis is the most common presentation, manifested by blurred vision, eye redness, photophobia, pain, and “mutton fat” keratic precipitates on slit-lamp examination. Involvement is usually bilateral, which distinguishes it from the unilateral uveitis seen in HLA-B27-associated spondyloarthritis. Other ophthalmologic manifestations include interstitial keratitis, posterior uveitis, pars planitis (“snowballing” on slit-lamp examination), scleral plaques, lacrimal gland enlargement (15% to 28%), optic neuropathy, and corneal/conjunctival nodules. Approximately 20% of patients with uveitis experience some visual loss. Eye manifestations are treated with topical, injectable, and systemic corticosteroids. Topical corticosteroids and cycloplegics are usually sufficient for anterior uveitis, although granulomatous involvement of ocular structures and posterior segment inflammation require oral corticosteroid or periocular steroid injections. Azathioprine, mycophenolate mofetil, methotrexate, leflunomide, infliximab, and rituximab have all been effective for treatment of corticosteroid-refractory disease.

Cutaneous involvement

Skin involvement occurs in up to 30% of cases and can be divided into specific and nonspecific categories.⁹ Specific lesions demonstrate granulomatous inflammation on biopsy. The most common specific skin manifestation is hyperpigmented maculopapular lesions (2 to 5 mm) commonly located on the face, nape of the neck, and upper back. Other specific lesions include skin plaques and annular lesions, which are associated with chronic disease and a poor prognosis when they occur on the head and neck. Scars and tattoos can become infiltrated with sarcoidosis. Subcutaneous Darier-Roussy sarcoidosis presents as nodules deep in the dermis and subcutaneous tissue and can remit spontaneously. Lupus pernio has a predilection for black and Puerto Rican women and is the most characteristic specific skin manifestation of sarcoidosis (Fig. 166.2). Lesions are indurated and violaceous, occurring primarily on the nose, cheeks, ears, lips, and fingers. They tend to be slowly progressive and can be disfiguring. Lupus pernio has a

significant association with chronic upper respiratory tract involvement, pulmonary fibrosis, and bony lesions of the phalanges. Conversely, nonspecific skin lesions are inflammatory but do not demonstrate granulomas on histologic examination. Erythema nodosum is the most common nonspecific skin manifestation, occurring in 10% of patients with sarcoidosis. It is seen more commonly in young white females and usually is associated with an acute presentation and benign course. A variety of atypical lesions also may be seen. In general, chronic sarcoid skin lesions do not ulcerate, itch, or cause pain. Topical corticosteroids and monthly intralesional injections of triamcinolone are often effective therapy for small sarcoid papules or plaques. Larger, disfiguring skin lesions require systemic corticosteroid therapy, antimalarials (chloroquine and hydroxychloroquine; overall response rate of 35%), methotrexate, and/or infliximab. Thalidomide, pentoxifylline, apremilast, minocycline, psoralens and ultraviolet A phototherapy, and retinoids have been anecdotally successful in a few patients with refractory sarcoid skin lesions.⁹

Cardiac involvement

Symptomatic cardiac involvement occurs in 5% of patients with sarcoidosis, but cardiac lesions are considerably more common at autopsy (20% [United States] to 67% [Japan]).¹⁰ It is more common in patients with severe disease and frequently coexists with neurosarcoidosis. Sarcoidosis may affect any part of the heart except the valves. Manifestations include sudden death, conduction disturbances, papillary muscle dysfunction, infiltrative cardiomyopathy with congestive heart failure, cor pulmonale due to severe restrictive lung disease, and pericarditis. All sarcoidosis patients should have a baseline electrocardiogram, which should be repeated annually or with development of symptoms. Electrocardiographic abnormalities occur in over 50% of patients with cardiac involvement, manifesting as various dysrhythmias, conduction disturbances, and nonspecific ST- and T-wave changes. Twenty-four-hour Holter monitoring and exercise electrocardiography should be performed in all patients with arrhythmias, conduction disturbances, or palpitations. In those with conduction blocks or arrhythmias, electrophysiologic studies are needed in performing the risk assessment for sudden cardiac death. Two-dimensional and M-mode echocardiography in patients with cardiac sarcoidosis can show granulomatous inflammation in the myocardium (hyperechogenicity of the ventricular septum), left ventricular hypertrophy and dyskinesis, restrictive cardiomyopathy, valvular incompetence due to papillary muscle dysfunction, and asymptomatic pericardial effusions (20% of patients). Cardiac magnetic resonance imaging (MRI) with gadolinium enhancement and fasting cardiac positron emission tomography with fluorine-18-labeled fluorodeoxyglucose (FDG-PET) are important new modalities used in the assessment of cardiac sarcoidosis.¹¹ Endomyocardial biopsy findings are often negative (80%), because cardiac sarcoid lesions tend to be heterogeneous and have a predilection for the left ventricular free wall.

Symptomatic cardiac sarcoidosis must be treated early and aggressively. Heart failure and/or sudden cardiac death due to conduction block or ventricular arrhythmias account for 75% of deaths due to cardiac sarcoidosis. Therefore treatment with high-dose prednisone (60 mg/day or more) should be initiated in patients with ventricular arrhythmias or cardiomyopathy.^{3,10} Antiarrhythmic agents and medications for heart failure should be used as adjunctive therapies. Cardiac MRI and FDG-PET may be useful in monitoring the response to therapy. In patients with severe or refractory disease, high-dose pulse methylprednisolone, azathioprine, methotrexate, and cyclophosphamide have been used with some success. Implantable pacemakers are indicated in those at risk of sudden cardiac death, and heart transplantation has been used in patients in whom medical management has failed.

Nervous system involvement

Symptomatic involvement of the central or peripheral nervous systems occurs in approximately 5% to 10% of patients, although signs of such involvement are three times more common at autopsy.^{12,13} Up to 33% of patients who develop neurosarcoidosis have neurologic manifestations either preceding the disease or at the time sarcoidosis is first diagnosed. Neurosarcoidosis has a predilection for the base of the brain and can occur without pulmonary or systemic features of sarcoidosis. Unilateral cranial nerve palsy, most frequently of the seventh nerve, is the most common presentation (50% of cases). *Heerfordt syndrome* is the combination of fever, parotid enlargement, arthritis, uveitis, and facial nerve palsy. It occurs most commonly in males and usually has a poor prognosis. Other features of neurosarcoidosis include leptomeningeal involvement (20% to 40%), other cranial neuropathies, hypothalamic and pituitary lesions, localized mass lesion, myelopathy (fewer than 10%), seizures, psychiatric and cognitive

dysfunction, as well as other less common manifestations. Peripheral neuropathy documented by electromyography and nerve conduction studies occurs in 8.5% to 24% of patients with neurosarcoidosis. Chronic sensorimotor polyneuropathy is the most common presentation, although mononeuritis multiplex, pure sensory neuropathy, intercostal neuritis, small-fiber neuropathy, and acute Guillain-Barré syndrome may occur.

MRI with gadolinium enhancement is the best imaging technique to evaluate sarcoid involvement of brain parenchyma, meninges, or spinal cord, as well as response to therapy.¹⁴ FDG-PET may be useful to identify areas of activity to biopsy. Cerebrospinal fluid analysis can show elevated opening pressure (10%), elevated protein level of up to 250 mg/dL (70%), normal or low glucose concentration (20%), lymphocytic pleocytosis (50%), high immunoglobulin G index, and oligoclonal bands (50% or more). Although the finding is nonspecific, the cerebrospinal fluid can show an elevated level of angiotensin-converting enzyme (ACE). Brain biopsies are invasive and may not reveal definitive pathologic changes. The prognosis of neurosarcoidosis is guarded, and symptoms can be chronic or relapsing (32%). Mortality can be as high as 10% to 15%.

Neurosarcoidosis is treated with oral prednisone (60 to 80 mg/day).^{12,13} Antiseizure medications are used as adjunctive therapy in patients with seizures. Patients with severe and refractory disease have been treated with immunosuppressive therapy similar to that used in cardiac sarcoidosis. Uncontrolled reports have suggested that antimalarial agents, methotrexate, azathioprine, mycophenolate mofetil, cyclophosphamide (oral and monthly pulse), cyclosporine, infliximab, and cranial irradiation may be effective.¹³ Surgical intervention is necessary for hydrocephalus and mass lesions that are expanding or causing increased intracranial pressure. Because of the possibility of devastating sequelae and the reactivation of neurosarcoidosis, most patients are maintained on low-dose prednisone and a second immunomodulatory medication for life.

Musculoskeletal involvement

Joints

Musculoskeletal manifestations, including arthritis and peri arthritis, occur in 4% to 38% of patients. Arthralgias are considerably more common (70%). Arthritic involvement is generally divided into acute and chronic types. The most common form of joint involvement is an acute polyarthropathy/peri arthritis. This type of arthritis may be migratory, resembling rheumatic fever; intermittent, resembling palindromic rheumatism; or additive, resembling rheumatoid arthritis. It can precede other manifestations of sarcoidosis by several months. More commonly, however, it is nonmigratory and accompanied by other features of acute sarcoidosis. Among patients with acute sarcoidosis who have bilateral hilar adenopathy and erythema nodosum (Löfgren syndrome), 70% have this form of polyarthropathy/peri arthritis, often associated with fever (66%) and uveitis (Fig. 166.3).^{15,16} This presentation most commonly occurs in young white and Puerto Rican women and is rare in blacks. Large joints, especially the ankles and knees, are most frequently affected, although other peripheral large and small joints may also be involved. Palpation of periarticular tissues elicits severe tenderness consistent with a peri arthritis. Joint radiography and ultrasonography show soft tissue swelling without bony changes. Arthrocentesis reveals no or only minimal synovial fluid, which is mildly inflammatory with a lymphocyte predominance. Synovial biopsy specimens show mild, nonspecific synovitis without granuloma formation.

Patients with acute polyarthropathy at presentation have or will develop erythema nodosum in 50% to 75% of cases. Bilateral hilar adenopathy is present in over 90% of these individuals at disease onset, but in some patients it does not develop for several weeks, which makes the diagnosis of sarcoidosis difficult. The acute form of joint involvement is usually associated with a benign course. Joint pain may resolve within weeks or persist for several months (average, 3 months); however, 10% to 15% of patients have several recurrences or persistently active joint disease. Patients with a normal serum ACE level at diagnosis (70% to 85% of patients) are most likely to experience complete resolution of their disease without recurrences. Acute arthritis/peri arthritis (Löfgren syndrome) usually requires no specific therapy other than analgesics or nonsteroidal antiinflammatory drugs (NSAIDs) such as indomethacin. Low-dose prednisone may be needed in patients with severe symptoms. Colchicine appears to shorten episodes in some patients.

Chronic sarcoid arthritis without involvement of adjacent bone is most likely to occur in black patients (Fig. 166.4).^{16,17} This type of joint involvement is uncommon (1% to 4%) and usually accompanies the slower-onset, more chronic and systemic form of sarcoidosis with cutaneous lesions, parenchymal pulmonary disease, and elevated ACE levels. The arthritis may be mild and transient or recurrent and protracted. Monoarthritis is relatively

Fig. 166.3 Löfgren syndrome. At presentation the patient had knee arthritis, erythema nodosum, and bilateral hilar adenopathy evident on a chest radiograph.

Fig. 166.4 Chronic polyarthritis. At presentation the patient had long-standing sarcoidosis and involvement of the interphalangeal joints and nails.

unusual so infection and crystalline arthropathies should always be considered. Oligoarthritis is typically nondestructive, involving the shoulders, wrists, knees, ankles, and/or small joints of the hands and feet. A chronic polyarthritis resembling rheumatoid arthritis and sacroiliitis mimicking spondyloarthritis or mycobacterial infection are rare presentations. Radiographs typically show soft tissue swelling, but bony destruction is uncommon. Arthrocentesis reveals a mildly inflammatory fluid (5000 cells/mm^3) with a mononuclear cell predominance. In contrast to acute sarcoid arthritis, in chronic sarcoid arthropathy synovial biopsy specimens characteristically show granulomatous inflammation. Tenosynovitis of the wrist, ankle,

patella, or Achilles tendons can also occur (5% to 13% of cases). For chronic synovitis, low-dose corticosteroids may be helpful if NSAIDs or analgesics fail. Chloroquine, hydroxychloroquine (400 mg/day), azathioprine, leflunomide, methotrexate (7.5 to 20 mg/wk), infliximab, and rituximab have been used successfully in patients with severe musculoskeletal manifestations refractory to corticosteroids.^{3,15-18}

Bone

The frequency of bone involvement ranges from 3% to 13%.¹⁶⁻¹⁸ Bone changes may be present at disease onset but are more frequently seen in patients with chronic and established disease. Women are affected more than men (2:1), and blacks are affected more than other racial groups. Bone lesions occur frequently in patients with lupus pernio and/or other granulomatous skin lesions and predict a poor prognosis with excessive mortality. There is a predilection for the phalanges of the hands and feet. Other bones can be involved, particularly the nasal bones in patients with lupus pernio and the calcaneus, which causes heel pain mimicking spondyloarthritis. The skull, vertebrae, ribs, pelvis, sternum, maxilla, and distal ends of long bones are rarely affected. Sclerotic lesions of the axial skeleton occur mainly in middle-aged black patients and may mimic metastatic disease.

Bone lesions of the phalanges can be lytic, permeative, and/or destructive and tend to be bilateral in distribution. Lytic lesions appear as rounded, “punched-out” bone defects on radiographs and are most frequently located at the ends of the proximal and middle phalanges (Fig. 166.5). Permeative lesions reflect granulomatous involvement of cortex and trabeculae of the phalangeal shafts, resulting in a reticular, lacelike appearance on radiographs. This may result in the phalangeal shafts becoming tubular. In advanced cases sclerosis or fractures may develop or joints may be affected owing to subchondral bony involvement and collapse. Notably, sarcoid bone lesions are not associated radiographically with periostitis and rarely with sequestra, which helps to separate sarcoidosis from chronic osteomyelitis. Technetium-99m diphosphonate bone scanning, MRI, and FDG-PET may detect unsuspected osseous involvement because over 50% of bony lesions are asymptomatic.

It is not known why sarcoidosis has a predilection for the phalanges. Pathologically, granulomatous infiltration into the marrow results in rarefaction of the trabeculae. In the cortical bone there is irregular resorption, with enlargement of haversian canals containing granulomas. Occasionally, granulomatous inflammation can extend into surrounding tissues, causing infiltration of tendon sheaths. MRI can distinguish soft tissue involvement from bony lesions. Granulomatous involvement of tendon sheaths can result in sarcoid dactylitis, with swelling over the affected digits associated with pain and stiffness. The overlying skin can be erythematous, and when the terminal phalanges are involved the nails may become thickened and dystrophic. Clubbing involving one or more digits has been described. Osteosarcoidosis responds poorly to therapy.¹⁶⁻¹⁸ Corticosteroids decrease swelling but do not completely normalize bony destruction. Hydroxychloroquine, chloroquine, methotrexate, and anti-TNF agents have been reported anecdotally to be helpful adjunctive therapies.¹⁹

Muscle

Asymptomatic muscle involvement is common (20% to 80% of cases), whereas symptomatic involvement occurs in fewer than 3% of patients.^{16,18,20} A random muscle biopsy in a sarcoidosis patient without myopathic symptoms will show granulomas in up to 80% of cases and can be used for tissue diagnosis. There are three forms of symptomatic muscle disease. The most common form is a chronic myopathy. This evolves slowly over several years, resulting in symmetric proximal muscle weakness and wasting, similar to muscular dystrophy. Neurogenic atrophy due to granulomatous infiltration of nerves can occur. In patients with muscle involvement, electromyography shows myopathic changes, but muscle enzyme levels are frequently normal or only minimally elevated. Concurrent cardiac muscle involvement is often seen in patients with this type of myopathy.

Acute granulomatous myositis and muscle nodules are the other two types of symptomatic muscle involvement but are unusual manifestations. Acute sarcoid myositis is rare, occurring mostly in young black females. Patients have signs and symptoms similar to those of polymyositis with myalgias, proximal muscle weakness, muscle tenderness, high levels of muscle enzymes, and muscle necrosis/granulomatous inflammation on biopsy. Many patients have fever and an elevated erythrocyte sedimentation rate at the time of presentation. Palpable granulomatous nodules and mass or tumor-like lesions may cause pain, stiffness, and cramping of the involved muscle. Muscle MRI shows a characteristic “dark star” sign on axial images.

The response of acute granulomatous myositis to treatment with corticosteroids is good, and the course is usually benign. However, in chronic

Fig. 166.5 Bone cysts and sarcoid dactylitis. (a) Radiograph of small bones of the hand showing bone cysts in an asymptomatic patient with bilateral hilar adenopathy. (b) Dactylitis with underlying bone cyst. (c) Resolution of dactylitis after treatment with oral prednisolone.

myopathy and nodular disease the response to therapy is unpredictable, with variable remissions and exacerbations requiring continued immunosuppression and adjustments of the corticosteroid dose.

Other organ system involvement

Constitutional symptoms of fever, fatigue, weight loss, and/or malaise occur in over a third of patients. Sarcoid granulomas have been reported to involve virtually any organ.³ Peripheral lymphadenopathy is common and usually nontender. Sarcoidosis of the upper respiratory tract can involve the oral, pharyngeal, and nasal mucosa, leading to obstruction, anosmia, and sometimes disfigurement.²¹ Parotid and minor salivary gland enlargement occurs in 6% and can cause sicca symptoms, mimicking Sjögren syndrome.²² The thyroid can be infiltrated, and the presence of antithyroid antibodies has been reported. The liver and spleen show granulomas on biopsy in 50% to 80% of patients.²³ The alkaline phosphatase level is frequently elevated (33%), but significant liver dysfunction is unusual. Cholestasis can result from granulomatous cholangitis or hepatic hilar adenopathy. Hepatosplenomegaly can occur and is associated with progressive fibrotic disease in other organs. Portal hypertension has been reported as a result of granulomatous phlebitis of hepatic or portal veins.

Sarcoidosis can cause granulomatous ulcers or masses in the gastrointestinal tract from the esophagus to the rectum. Pancreatic and peritoneal sarcoidosis are rare. Renal involvement is also rare. Granulomatous interstitial nephritis, glomerulonephritis, and amyloidosis may also occur. All areas of the male and female genitourinary tract have been reported to be involved in case series. Sarcoidosis has been rarely associated with vasculitis, and all sizes of blood vessels can be involved.²⁴ Black and Asian children are more likely to have large-vessel involvement that can resemble Takayasu arteritis.

Overproduction of 1,25-dihydroxyvitamin D can lead to increased intestinal absorption of calcium, causing hypercalcemia (10% to 15%), hypercalciuria (40% to 60%), nephrocalcinosis, nephrolithiasis (10%), and renal insufficiency.^{3,25} The risk of nephrolithiasis is 20% higher than in the general population. Hypercalcemia (more than 11 mg of calcium per deciliter), elevated serum creatinine concentration, and nephrolithiasis are indications for corticosteroid therapy at dosages of 20 to 40 mg/day of prednisone. Both hypercalcemia and hypercalciuria usually respond rapidly within 7 to 10 days. Antimalarials and ketoconazole (600 to 800 mg/day) act more slowly but produce a more sustained lowering of calcium level after cessation of therapy. Consumption of a low-calcium diet, avoidance of vitamin D supplements, and limited exposure to sunlight are helpful adjunctive measures. Patients should keep well hydrated to help prevent nephrolithiasis.

CHILDHOOD SARCROIDOSIS

Children of both sexes develop sarcoidosis less commonly than adults. The clinical manifestations in older children are similar to those in adults. However, in children younger than 5 years the characteristic presentation includes mild constitutional symptoms; painless, boggy, and effusive large-joint polyarthritis and tenosynovitis; skin lesions; uveitis; and lymphadenopathy and splenomegaly without typical lung disease.²⁶ This presentation must be differentiated from the rare autosomal dominant familial granulomatous disorder Blau syndrome, which is caused by a genetic mutation of the NOD2/CARD15 protein. Children with sarcoidosis usually have a spontaneous resolution of disease, but some experience residual complications. Corticosteroids with or without methotrexate are the treatment of choice for children with severely symptomatic or progressive disease.

SARCROIDOSIS ASSOCIATIONS

A variety of autoimmune disorders that may occur in association with sarcoidosis have been described in case reports.²⁷ These include rheumatoid arthritis, systemic sclerosis, systemic lupus erythematosus, Sjögren syndrome, spondyloarthritis, inflammatory bowel disease, primary biliary cirrhosis and other autoimmune liver diseases, autoimmune cytopenias, autoimmune thyroiditis alone or as part of polyglandular autoimmune syndrome type III, polymyositis, inclusion body myositis, insulin-dependent diabetes mellitus, dermatitis herpetiformis, vitiligo, myasthenia gravis, and pernicious anemia. Sarcoidosis has also been associated with common variable immunodeficiency and 5q myelodysplasia, and appears as part of the immune reconstitution syndrome in patients with human immunodeficiency virus (HIV) receiving highly active antiretroviral therapy. It has been reported to occur before or simultaneously with various malignancies or after chemotherapy. Malignant lymphoma, lung cancer, testicular cancer, and lymphoproliferative disorders have been reported most often. Medication-induced sarcoidosis has been described after treatment with interferon- α (IFN- α) for hepatitis C, interleukin-2 (IL-2) for renal cell carcinoma, anti-TNF therapy for rheumatoid arthritis, and IFN- γ . Notably, each of these therapies promotes a T helper type 1 (Th1) response.

INVESTIGATIONS

The diagnosis of sarcoidosis is made by a combination of clinical, radiologic, and laboratory findings and confirmed by characteristic histologic findings.⁵

Patients with a classic presentation such as Löfgren syndrome may not need to undergo tissue biopsy. However, in all doubtful cases and in cases in which immunosuppressive treatment is likely to be needed, histologic confirmation of disease in one organ is essential. The requirement that more than one organ be involved to confirm the diagnosis of sarcoidosis does not require a second organ to be sampled. Clinical criteria for organ involvement without a biopsy have been published.²⁸ Once the diagnosis is established, the American Thoracic Society recommends the comprehensive baseline evaluation presented in [Box 166.1](#).⁵

Laboratory tests

Laboratory evaluation of patients with sarcoidosis shows many abnormalities.^{2,3} Most patients have anemia of chronic disease and lymphopenia. Some (up to 25%) may have eosinophilia. Leukocyte and platelet counts are normal (95%) unless there is significant bone marrow involvement (5%), hypersplenism, or another associated autoimmune disease. Chemistry panels are performed to rule out diabetes insipidus due to pituitary involvement or renal insufficiency due to nephrocalcinosis. Hypercalciuria occurs three times more commonly than hypercalcemia and places the patient at risk of nephrolithiasis and renal insufficiency.²⁹ Liver-associated enzyme levels are abnormal in up to one third of patients, with elevations in alkaline phosphatase and γ -glutamyl transferase occurring more often than elevations in aminotransferase levels.

Serologic abnormalities, including elevated erythrocyte sedimentation rate, increased C-reactive protein level, and hypergammaglobulinemia (30% to 80%), are common during active sarcoidosis. Low-titer rheumatoid factor is seen in up to 38% of patients, depending on the method used, and is more likely in those with chronic lung disease. A positive antinuclear antibody test result with a speckled pattern of immunofluorescence in low titer is seen in up to 34% of patients. Tests for antibodies against specific nuclear and cytoplasmic (ANCA) antigens typically yield negative results. Antiphospholipid antibodies have been reported, particularly in patients with extra-thoracic organ involvement. Tuberculin and anergy skin testing show that many patients with active disease are anergic.

ACE levels are elevated in 40% to 90% of sarcoidosis patients. Elevations correlate with active pulmonary disease and normalize with successful therapy. This enzyme is produced by epithelioid cells and alveolar macrophages at the periphery of granulomas in response to an ACE-inducing factor released by T lymphocytes. ACE may contribute to the formation of granulomas by producing angiotensin II locally, which is chemotactic for macrophages and enhances phagocytosis. Elevated ACE levels are not specific for sarcoidosis and may be caused by other diseases, such as hyperthyroidism, Gaucher disease, diabetes mellitus, leprosy, α_1 -antitrypsin deficiency, Kaposi sarcoma in HIV-infected patients, silicosis, hypersensitivity pneumonitis, cirrhosis, histoplasmosis, and asbestosis. Additionally, ACE levels are influenced by ACE gene polymorphisms (DD allele).³⁰ Therefore an elevated ACE level may be supportive, but not diagnostic, of sarcoidosis.

BOX 166.1 RECOMMENDED INITIAL EVALUATION OF PATIENTS WITH SARCOIDOSIS

1. History (occupational and environmental exposure, symptoms)
2. Physical examination
3. Posteroanterior chest radiography
4. Pulmonary function tests: spirometry and DL_{CO}
5. Peripheral blood counts: White blood cells, red blood cells, platelets
6. Serum chemistries: calcium, liver enzymes (alanine aminotransferase, aspartate aminotransferase, alkaline phosphatase), creatinine, BUN
7. Urine analysis
8. ECG
9. Routine ophthalmologic examination
10. Tuberculin skin test

BUN = blood urea nitrogen; DL_{CO} = diffusing capacity of the lung for CO; ECG = electrocardiogram.

From Statement on Sarcoidosis. Joint statement of the American Thoracic Society (ATS), the European Respiratory Society (ERS) and the World Association of Sarcoidosis and other Granulomatous Disorders (WASOG) adopted by the ATS Board of Directors and by the ERS Executive Committee, February 1999. *Am J Respir Crit Care Med* 1999;160:736-755.

Imaging

The chest radiographic staging system has been described earlier (see section on [respiratory tract involvement](#)). The HRCT scan is more sensitive and correlates with histologic and pulmonary function test abnormalities more closely than the plain chest radiograph.³¹ Plain bone radiographs and technetium-99m diphosphonate scanning can detect bone lesions. MRI with gadolinium enhancement can be used to detect brain involvement, myocardial disease, muscle disease, and bone involvement.³¹ FDG-PET is a sensitive test for detecting sarcoid involvement of multiple tissues and showing organs that are candidates for diagnostic biopsy.³² Gallium-67 citrate scans are not specific and are no longer routinely used for the diagnosis of sarcoidosis.

Biopsy

Tissue biopsy is the gold standard for confirming a clinical/radiographic diagnosis of sarcoidosis. Tissue biopsy should be performed in any patient who has an atypical presentation or for whom therapy is being considered, to exclude infection or malignant disease. Transbronchial, lymph node, and skin biopsies are the most common, but a specimen can be obtained from any clinically involved organ.³³ The diagnostic yield is as follows:

- Transbronchial lung biopsy with normal findings on chest radiograph, 30% to 50%
- Transbronchial lung biopsy with abnormal findings on chest radiograph, more than 90%
- Endobronchial biopsy, 40% to 60%
- Lymph node biopsy, more than 90%
- Endobronchial ultrasound-guided transbronchial fine-needle aspiration of intrathoracic lymph nodes, 83%
- Minor salivary gland biopsy, 36%
- Parotid biopsy, 93%
- Muscle biopsy, 50% to 80%
- Liver biopsy, 50% to 80%
- Synovial biopsy in chronic arthropathy, 80%
- Biopsy of conjunctival nodules, 67%; lacrimal gland, 10% to 55%
- Skin biopsy, more than 90%
- Endomyocardial biopsy, 20%

The characteristic histologic finding is that of well-circumscribed non-caseating granulomas of the epithelioid type ([Fig. 166.6](#)). However, the presence of noncaseating granulomas is not diagnostic of sarcoidosis until other granulomatous diseases are excluded (see section on [differential diagnosis](#)). Notably, a few sarcoidosis patients may have granulomas with some minor necrosis on biopsy. Use of the Kveim-Siltzbach skin test is no longer recommended.

Additional tests

Three tests that should be done as a baseline assessment in all patients are (1) an electrocardiogram, (2) an ophthalmologic examination with a slit lamp to rule out asymptomatic abnormalities, and (3) a 24-hour urine collection for calcium to rule out hypercalciuria. Fluorescein angiography is helpful to document posterior uveitis. Pulmonary function tests, bronchoalveolar lavage fluid cell analysis,³⁴ Holter monitoring, and echocardiography are described in the sections discussing respiratory tract and cardiac involvement, respectively.

DIFFERENTIAL DIAGNOSIS

Several diseases can result in clinical presentations and granulomas on biopsy specimens that resemble those of sarcoidosis.^{2,3} Acute histoplasmosis can simulate Löfgren syndrome and must be excluded by serologic studies and cultures. Acute arthritis with erythema nodosum, but without hilar adenopathy, can occur in inflammatory bowel disease, coccidioidomycosis, histoplasmosis, psittacosis, and reactions to various medications. The pattern of arthritis in these patients is also similar to that seen in sarcoidosis.

In patients with more insidious presentations other diseases need to be considered, depending on the organ involved. In patients with pulmonary disease chronic berylliosis should be excluded by lack of a clinical history of exposure and a beryllium lymphocyte proliferation test. Hypersensitivity pneumonitis is ruled out by lack of a history of occupational and environmental exposure and results of serologic tests for precipitins. Reactions to drugs (methotrexate, IFN- α , IFN- γ , anti-TNF agents, IL-2) and other inorganic agents, such as metals (titanium, aluminum, zirconium), silica, and talc, are excluded by good history taking. Fungal serologic studies or stains

Fig. 166.6 Sarcoid granulomas. (a) Histologic section of lymph node showing noncaseating epithelioid and giant cell granulomas. (b) Histologic section from a patient with acute sarcoidosis showing noncaseating granulomas with central eosinophilic necrosis of collagen. There was subsequent natural resolution without treatment in this case.

or cultures for organisms rule out fungal and mycobacterial disease. Granulomatosis with polyangiitis (Wegener granulomatosis) is excluded by the absence of a positive result on the ANCA test and the absence of vasculitis on biopsy. Patients with eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome) have a history of asthma and prominent eosinophilia. Tissue biopsy results exclude lymphoma and eosinophilic granuloma. In patients with cutaneous granulomatous lesions treponemal infections, leprosy, tularemia, and leishmaniasis should be excluded by serologic studies and/or cultures. Granuloma annulare and granulomatous rosacea are ruled out clinically by lack of systemic involvement. Lupus vulgaris due to mycobacterial infection may mimic cutaneous plaques of sarcoidosis. Primary biliary cirrhosis can cause liver granulomas but is associated with antimitochondrial antibodies. Fungal or mycobacterial infections and brucellosis should be considered in patients with monoarticular, axial, or peripheral arthritis. Fungal and mycobacterial infections, leprosy, brucellosis, syphilis, granulomatosis with polyangiitis, eosinophilic granuloma, multiple myeloma, and lymphoma can cause bony lesions similar to those caused by sarcoidosis. Toxoplasmosis can mimic acute and chronic sarcoid myopathy, and various neoplasms and infections need to be excluded in patients with a muscle mass. Finally, granulomas in a single organ (e.g., idiopathic granulomatous hepatitis or panuveitis) without evidence of other organ involvement should not be diagnosed as sarcoidosis.

ETIOLOGY

The cause of sarcoidosis is unknown. Multiple environmental agents and genetic associations have been reported.

Environmental risk factors

Because the lung is most commonly involved, exposure to an airborne antigen is postulated. The ACCESS trial reported an increased risk of sarcoidosis in people with exposure to (1) water sources that serve as reservoirs for aerosolized microbial antigens (agriculture and water-damaged areas rich in molds); (2) metal industry (heavy metals and mycobacteria-contaminated metalworking fluids); (3) inorganic particulate matter (silicates); (4) insecticides.³⁵ Notably, chronic beryllium disease causes lesions in the lung (but not in other organs) that are histologically identical to those in sarcoidosis. Interestingly, multiple studies have shown that cigarette smoking decreases the probability of developing sarcoidosis. It is postulated that the acrolein (breakdown product of cyclophosphamide) in cigarette smoke is cytotoxic to lymphocytes trying to enter the lungs, which could account for the decreased prevalence of sarcoidosis in cigarette smokers.

Infectious agents have been associated with sarcoidosis.³⁶ Mycobacterial and propionibacterial nucleic acid have been recovered from sarcoid granulomas. Recently *Mycobacterium tuberculosis* DNA coding for a catalase-peroxidase protein (mKatG) has been found in sarcoid biopsy specimens (38%). Additionally, peripheral blood and lung T-cell responses as well as circulating immunoglobulin G against mKatG are increased in half of sarcoid patients. Other infectious agents have been proposed. However, the inability of any of these agents to cause sarcoidosis in animal models, the diversity of tissues involved in sarcoidosis that are not typically affected by some of

these organisms, the lack of response to antibiotics but improvement with immunosuppressive agents, and the failure of the prevalence of sarcoidosis to decrease in countries where bacille Calmette-Guérin vaccination is used are all evidence against a single infectious agent causing sarcoidosis.

Genetic risk factors

Genetic factors also play a role in the racial and ethnic variations in prevalence, clinical presentations, and severity of sarcoidosis.³⁷ Reports of several hundred families with two or more affected members are considered the strongest evidence for a genetic component to this disease. The ACCESS study showed that first-degree relatives of sarcoidosis patients had over a five times increased relative risk of developing sarcoidosis.³⁸ In addition, the concordance rate is reported to be two to four times higher in monozygotic than in dizygotic twins. Overall, the absolute risk that a sibling or parent of a sarcoidosis patient will develop sarcoidosis is approximately 1%. Despite this increased risk of sarcoidosis within families, affected sibling pairs show minimal concordance in clinical manifestations and outcomes.

The intraracial heterogeneity of clinical manifestations and prognoses makes it unlikely that a single gene is responsible for sarcoidosis.³⁷ HLA genes confer the most important genetic risk of susceptibility. HLA-DRB1*0301, HLA-DRB1*1101, HLA-DRB1*1201, and HLA-DRB1*1501 alleles have the strongest association with sarcoidosis risk. HLA-DRB1*0301/DQB1*0201 haplotype and CC chemokine receptor 2 (CCR2) haplotype 2 are highly associated with Löfgren syndrome and a benign course, whereas HLA-DRB1*1501/DQB1*0602 haplotype is associated with a severe, chronically progressive course. Non-HLA candidate genes associated with disease in specific ethnic groups of sarcoidosis patients include certain alleles of TNF- α , CC chemokine receptors (CCR2, CCR5), butyrophilin-like 2 (BTNL2), and annexin 11. Genomewide association studies are likely to yield other candidate genes in other ethnic groups.

In summary, because of the multiple reported associations, sarcoidosis most likely represents the end result of an immune response to various ubiquitous environmental agents in a genetically predisposed host.

IMMUNOPATHOGENESIS

The noncaseating epithelioid granuloma is the histologic hallmark of sarcoidosis and is formed by a stepwise series of events.³⁹⁻⁴¹ Granuloma formation is a protective response to isolate poorly degraded antigens to prevent dissemination and/or further local tissue damage. Candidate antigens in sarcoidosis include environmental substances, microbial remnants, and misfolded serum amyloid A.

Step 1: Lymphocytic alveolitis

The initial event in sarcoidosis is thought to be the uptake and processing of a triggering antigen by antigen-presenting cells (type II alveolar epithelial cells, alveolar macrophages, and dendritic cells) bearing HLA class II molecules in the lower respiratory tract. The recognition of antigen by CD4+ T cells is considered to be a critical event in the development of disease. Alveolar macrophage secretion of chemoattractant cytokines (IL-8, IL-15,

IL-16) and chemokines (MIP-1/CCL3-4, RANTES/CCL5, IP-10/CXCL10) coupled with the cytokine-mediated (TNF- α , IFN- γ , IL-1, IL-15) upregulation of cell adhesion molecules (ICAM-1/CD54, ICAM-2/CD102, VCAM-1/CD106, α_1 integrin/CD49a) is central to the marked accumulation of inflammatory cells and recruitment of lymphocytes (CD4+ T cells) from the peripheral blood into the lung alveoli. Studies indicate that inflammatory alveolitis precedes granuloma formation and is associated primarily with the infiltration of CD4+ T lymphocytes and mononuclear phagocytes. In patients with established disease, there is a selective oligoclonal expansion of $\alpha\beta$ T cells in the lung, which exhibits a restricted T-cell receptor repertoire. This strongly suggests an antigen-specific immune response.

Step 2: Granuloma formation

The accumulation and activation of antigen-specific Th1 lymphocytes and the reciprocal suppression of the Th2 subset are the initial events in the development of granulomatous inflammation. Alveolar macrophage/dendritic cell-derived IL-12 with the help of IL-18 and IL-27 are critical to the differentiation of naive CD4+ T lymphocytes into Th1 cells. The polarized Th1 cells secrete the Th1 cytokines IL-2 and IFN- γ . IL-2 acts synergistically with IL-15 and TNF- α from macrophages to stimulate further T-lymphocyte proliferation and differentiation. Other T-lymphocyte cytokines stimulate macrophage recruitment, activation, and proliferation (granulocyte-macrophage colony-stimulating factor, MCP-1/CCL2, MIP-1/CCL3-4). The macrophage-derived cytokines, IL-12 and IL-18, coupled with IL-2, are potent stimulators of further IFN- γ production; this amplifies the immune response through its effects on multiple target cells including macrophages, which differentiate into secretory epithelioid cells at the center of the granuloma. Both IL-1 β and IFN- γ as well as several chemokines are important in the early recruitment stage of granuloma formation, whereas TNF- α may be particularly important in the later maintenance of granuloma formation and perpetuation of inflammation.

The sarcoid granuloma is well circumscribed, round or oval, noncaseating, and made up of compact, radially arranged epithelioid cells with pale nuclei (see Fig. 166.6). Some of the epithelioid cells fuse to form giant cells, typically of the Langhans type, in which the nuclei are arranged in an arc or circular pattern around a central granular zone. Stellate asteroids (entrapped collagen) and blue Schaumann inclusion bodies (altered lysosomes in giant cells) are occasionally observed. The center of the granuloma is composed of macrophage-derived epithelioid cells and CD4+ Th1 lymphocytes, whereas the outer zone contains many CD4+ and CD8+ T lymphocytes, fibroblasts, and interdigitating antigen-presenting cells entwined in bands of collagen.

Step 3: Granuloma resolution

The immunologic factors that determine the ultimate fate of sarcoid granulomas are poorly understood. Most granulomas resolve spontaneously or with therapy, whereas others are converted into a fibrotic scar. In the 25% of patients who develop progressive fibrosis there appears to be a shift from a Th1 to a Th2 cytokine (IL-10, IL-13) predominance at the local tissue level. Alveolar macrophages, mast cells, and neutrophils contribute to this fibrotic process by releasing superoxide radicals and proteases that cause local tissue injury. This is reflected clinically by the association of progressive lung fibrosis and a worse prognosis with neutrophilia in bronchoalveolar lavage fluid. Alveolar macrophages also secrete transforming growth factor- β (TGF- β) and CC motif ligand 18 (CCL18) among others. TGF- β induces local epithelial cells to transform into collagen matrix-producing fibroblasts. CCL18 attracts bone marrow-derived fibrocytes and regulatory T (Treg) cells from the peripheral blood. The fibrocytes differentiate and contribute to the fibroblast pool. Treg cells produce IL-10 in conjunction with other cells producing IL-13. These Th2 cytokines contribute to the transformation of alveolar macrophages into macrophages of the M2 phenotype, which secrete fibroproliferative cytokines (platelet-derived growth factor). This adds to the fibrogenic cytokines (fibroblast growth factor 2, insulin-like growth factor 1, fibronectin) produced by fibroblasts, causing more proliferation and collagen matrix production. The collagen matrix produced stimulates alveolar macrophages to make more CCL18, which results in a positive feedback loop.

NATURAL HISTORY AND PROGNOSIS

The natural history of untreated sarcoidosis is difficult to predict in an individual patient.⁴² The ACCESS study showed that the extent of organ involvement in most cases is defined at presentation, with fewer than 25% of patients developing new organ involvement within 2 years of follow-up.⁴³

Therefore, during the first 2 to 3 years after disease onset, certain tests (chest radiography, pulmonary function tests, calcium levels, any test that gives abnormal results initially) should be repeated every 3 to 6 months and others (eye examination, electrocardiography) every 12 months, or sooner if symptoms develop. Most patients (60%) undergo spontaneous remission within the first 3 years, with an additional 10% to 20% experiencing resolution with corticosteroid therapy. However, in 10% to 30% the course is chronic. Of those having a chronic course, half will have progressive pulmonary disease and half will display involvement of critical extrapulmonary organs, such as the eye, brain, and heart.

The probability of a spontaneous remission can be predicted by the patient's clinical and radiologic presentation. Up to 80% of patients who have hilar adenopathy alone (radiographic stage I disease) at presentation experience spontaneous resolution, and patients with Löfgren syndrome have the best overall prognosis for full remission within 2 years. Some 50% to 60% of patients with radiographic stage II disease experience remission, in contrast to fewer than 30% of those with stage III disease. The mortality rate of patients with pulmonary fibrosis (radiographic stage IV with vital capacity of less than 1.5 L) is 25% to 40%. Although the overall prognosis for sarcoidosis is good, at least 50% of patients have some degree of permanent organ dysfunction. In addition, there is a 5% mortality rate, with progressive pulmonary disease accounting for half and cardiac and neurologic disease causing the other half of all deaths from sarcoidosis. Of patients with cardiac or neurologic manifestations, up to 10% will die of organ failure. In Japan patients die of cardiac complications, whereas in the United States pulmonary disease causes most of the deaths.

In general, the more severe the involvement and the more organ systems involved at the time of diagnosis (three or more), the worse the prognosis. Extrapulmonary involvement (cardiac or neurologic involvement, lupus pernio, hypercalcemia, bone involvement) and pulmonary hypertension are poor prognostic signs, as are black race, disease onset after 40 years of age, and symptom duration of longer than 6 months.^{2,44}

MANAGEMENT

Because the cause of sarcoidosis is unknown, therapy is empiric.⁴⁴⁻⁴⁶ Whenever possible, patients with good prognostic signs should be observed for the first 3 to 6 months without immunosuppressive therapy because of the potential for spontaneous resolution. In patients with progressive disease, the recommended dosages of corticosteroids and adjunctive therapies vary, depending on the organ system involved (see individual organ system sections for specific therapies). There have been few controlled, randomized trials to establish the appropriate dose and duration of any therapy for sarcoidosis. Despite a lack of well-controlled clinical trials proving that corticosteroids improve long-term outcome, oral corticosteroids are used as first-line treatment for symptomatic and progressive stage II and III lung disease, malignant hypercalcemia, and severe ocular, neurologic, cardiac, skin, and musculoskeletal involvement.^{46,47} In patients who have an inadequate response to or unable to taper their corticosteroids, steroid-sparing agents alone or in combination are used.⁴⁸ Recently the monoclonal anti-TNF- α agents, particularly infliximab, have been found to be effective for various disease manifestations refractory to standard immunosuppressive therapy.⁴⁹⁻⁵¹ In case studies, rituximab has been used successfully for refractory disease, particularly when granulomatous mass lesions are present.^{52,53} Solid organ transplantation can be life-saving in patients for whom all medical therapies have failed.⁵⁴

Patients must be monitored for adverse effects and prophylactic measures used to prevent toxicities. Patients receiving high-dose corticosteroids should be given prophylaxis against *Pneumocystis jiroveci*. Osteopenia and osteoporosis due to dysregulated calcium metabolism and medications used in therapy can occur in up to two thirds of patients.⁵⁵ All sarcoidosis patients who are receiving corticosteroids or who are postmenopausal should have bone density testing, and bisphosphonate therapy should be started in those at risk of fractures. Vaccinations should be kept up to date. Depression is common (46% to 66%) and should be screened for and treated. Fatigue also is common (50% to 70%), can be disabling, and may respond to armodafinil or dexamethylphenidate.⁵⁶ Hypothyroidism, hypoxemia, depression, and sleep apnea are potential and correctable causes of fatigue.

MONITORING OF THERAPY

Many tests have been used to evaluate disease activity and response to therapy. However, no serologic test, including ACE level, has proved to be a reliable marker. The best assessment is through longitudinal observation

of symptoms and signs every 3 to 6 months. Testing, including chest radiography, HRCT, and measurement of pulmonary function and other parameters reflecting internal organ involvement, should be tailored to the patient. A response to therapy is defined as a decrease in symptoms, a reduction in radiographic abnormalities, and physiologic improvement (10% to 15% increase in forced vital capacity/total lung capacity, 20% increase in carbon dioxide diffusing capacity, or an improvement in gas exchange). MRI with gadolinium enhancement and FDG-PET may be useful in assessing activity in some organs that are difficult to access, such as heart, brain, and bone.

As therapy is tapered or discontinued, the physician must remain vigilant, given the tendency of sarcoidosis to relapse (50%) and/or affect new organs. Patients with previously poor prognostic signs and/or major organ involvement need lifelong follow-up.

Acknowledgment

The author wishes to thank Dr. Donald N. Mitchell for his figures from the previous editions of this chapter.

Relapsing polychondritis

■ SUSAN Y. RITTER ■ ANTONIOS O. ALIPRANTIS

- Relapsing polychondritis is a rare autoimmune disease of unknown etiology with episodic but potentially progressive inflammatory manifestations.
- Clinical features include inflammation of the auricular, nasal, laryngotracheal, costal, and articular cartilage and ocular and inner ear inflammation.
- Relapsing polychondritis may be associated with other autoimmune diseases and myelodysplastic syndrome and varies in its manifestations, course, and response to therapy.
- Involvement of the laryngotracheobronchial tree can lead to life-threatening airway compromise, and an associated systemic vasculitis may contribute significantly to morbidity and premature mortality.

HISTORY

Relapsing polychondritis (RP) is a rare disease of unknown etiology. The first clinical description of it is attributed to Jaksch-Wartenhorst, who in 1923 reported the case of a 32-year-old brewer with fever, asymmetric polyarthritis, and pain and swelling of his external ears.¹ This patient went on to develop external auditory canal stenosis, diminished hearing, and a saddle-nose deformity. A biopsy of the nasal septum showed a hyperplastic mucous membrane and the absence of cartilage. Jaksch-Wartenhorst called it *polychondropathia* and considered it to be a degenerative disorder. In 1960 Pearson and colleagues coined its currently accepted name, *relapsing polychondritis*, in a description of four cases and review of 12 previous reports.² They correctly identified RP as an intense inflammatory condition of both cartilaginous and noncartilaginous structures and recognized the severe pulmonary complications that can accompany this disease.

EPIDEMIOLOGY

RP is a rare disease, as demonstrated by the estimated annual incidence rate of 3.5 per million in Rochester, Minnesota.³ The peak age at onset is between 40 and 50 years, but cases have been observed in children and in the elderly (older than 80 years). It occurs with equal frequency in both sexes and all racial groups. Over the years, cases have been described in which RP is a primary disorder and in which RP is a secondary manifestation that occurs after the onset of the associated condition. In adults, over 30% of cases are associated with an existing autoimmune or hematologic disease (Box 167.1). In pediatric RP there is less likely to be an associated autoimmune disease, but there is often a strong family history of autoimmunity.⁴ The life expectancy of RP patients is reduced, with an estimated 5-year survival of 74% in one large series. In the subgroup of patients with systemic vasculitis the estimated survival is similar to that of patients with polyarteritis: 45% at 5 years. Infection and respiratory involvement are frequent and contribute to reduced survival.⁵

CLINICAL FEATURES

Otorhinolaryngeal disease

The classic clinical manifestation of RP is an acute unilateral or bilateral auricular chondritis. The onset is characteristic: warmth, swelling, and a red or violaceous discoloration of the cartilaginous portion of the pinna, sparing the earlobe (Fig. 167.1a). The episode lasts days to weeks and resolves with or without treatment. Over time, and with repeated attacks, the pinna loses its firmness and becomes soft and flops over (see Fig. 167.1b) or assumes a knobby, cauliflower-like appearance. In a series of 112 patients at the Mayo Medical School, auricular chondritis was the presenting feature in 39% and ultimately developed in 85% of patients.³ Inflammation of the nasal cartilage causes saddle-nose deformity (Fig. 167.2) and can also result in septal perforation. Similarly, inflammation in the larynx can result in hoarseness, dysphonia, and stridor, and “bamboo nodules” have been described.⁶ These bamboo nodules are white-yellow bilateral transverse lesions at the midportion of the vocal cords and have been seen in association with other autoimmune diseases. Hearing abnormalities occur in up to 30% of patients and can be caused by swelling of the external auditory canal, which leads to conductive deafness or vasculitis of the internal auditory artery resulting in neurosensory hearing loss (Table 167.1).⁷ Involvement of the inner ear structures can also result in vertigo.

Respiratory disease

Respiratory symptoms in RP are common and can be lethal. At onset, only 25% of patients have such symptoms, although 50% ultimately develop them. A recent large, retrospective chart review performed at an RP referral center found the prevalence of airway involvement to be 21%.⁸ Tenderness of the thyroid cartilage and the anterior trachea, hoarseness, persistent cough, choking spells, wheezing, and dyspnea on exertion can occur. Inflammation of the tracheobronchial tree leads to varying degrees of localized (Fig. 167.3) or diffuse obstruction, and damage to the cartilaginous rings can cause a dynamic obstruction leading to respiratory difficulty. Strictures usually form in the subglottic region, causing increased susceptibility to secondary infections. The reported mortality from respiratory complications varies from 10% to 50%, but the lower figure is probably more realistic.^{5,7,9-12} The influence of newer immunomodulatory agents, including biologic therapies, on the progression of respiratory disease in RP is promising but still unclear.¹³

Musculoskeletal symptoms

The arthritis of RP is episodic, seronegative, asymmetric, and oligoarticular or polyarticular. It can occur before, during, or after the diagnosis is established. It is a presenting feature in 30% of cases and ultimately develops in 75%. The episodes may last weeks to months, but the arthritis is nondeforming and nonerosive and may not correlate with the extraarticular disease manifestations. The joints most commonly involved are the ankles, followed by the wrists, proximal interphalangeal and metacarpophalangeal joints, elbows, and metatarsophalangeal joints. Inflammation of the costochondral cartilages may lead to a pectus deformity. Because RP may accompany another connective tissue disease, the patient may have the musculoskeletal manifestations of the associated disease as well.^{2,5,7,9,14} Interestingly, unlike juvenile inflammatory arthritis, the arthritis in pediatric RP does not appear to affect growth.⁴

Cardiovascular disease

The cardiovascular system is involved in fewer than 10% of RP cases. The spectrum of vasculitis associated with RP is broad, with small-vessel disease

BOX 167.1 CONDITIONS ASSOCIATED WITH RELAPSING POLYCHONDritis

- Rheumatoid arthritis
- Systemic lupus erythematosus
- Scleroderma
- Sjögren syndrome
- Overlap connective tissue disease
- Ankylosing spondylitis and sacroiliitis
- Psoriatic arthritis
- Reactive arthritis
- Antineutrophil cytoplasmic antibody-associated granulomatous vasculitis
- Polyarteritis nodosa
- Churg-Strauss vasculitis
- Behçet syndrome
- Myelodysplastic syndromes
- Lymphoma
- Inflammatory bowel disease
- Primary biliary cirrhosis

Fig. 167.1 Otorhinolaryngeal disease in relapsing polychondritis. (a) The pinna of the ear becomes inflamed: note the sparing of the noncartilaginous portion of the ear. (b) Recurrent attacks cause loss of cartilage, with the ear flopping over.

Fig. 167.2 Otorhinolaryngeal disease in relapsing polychondritis. The saddle-nose deformity is caused by damage to the nasal bridge.

TABLE 167.1**Clinical manifestations of relapsing polychondritis**

Finding	Frequency (%)	
	Initial	Total
Auricular chondritis	39	85
Saddle-nose deformity	18	29
Hearing loss	9	30
Arthritis	36	52
Costochondral cartilage inflammation	2	2
Nasal cartilage inflammation	24	54
Ocular inflammation	19	51
Scleritis/episcleritis	19	47
Laryngotracheal-bronchial disease	26	48
Laryngotracheal stricture	15	23
Systemic vasculitis	3	10
Valvular dysfunction	0	6
Cutaneous features	7	28

Adapted from Isaak BL, Liesegang TJ, Michet CJ Jr. Ocular and systemic findings in relapsing polychondritis. *Ophthalmology* 1986;93:681-9.

Fig. 167.3 Localized tracheobronchial obstruction due to relapsing polychondritis. (a) The radiograph shows both narrowing in the larynx above the tracheostomy tube and tracheal stenosis below (arrowheads). (b) Computed tomographic scan of the trachea shows the thickening of the tracheal wall due to inflammatory changes (arrowheads). Note how the posterior, noncartilaginous portion of the trachea is spared.

presenting as cutaneous leukocytoclastic vasculitis and large-vessel disease, similar to Takayasu arteritis, occurring. A systemic polyarteritis nodosa in medium-sized vessels has also been observed in 9% of patients. In some cases, the vasculitis may present before the diagnosis of RP can be made. Aneurysms of the thoracic and abdominal aorta can occur. Aortitis causes thinning of the media and leads to dilatation of the root of the aorta and leakage of the aortic valve. The aortic and mitral valves can be sites of inflammation as well, with incompetence of the valve developing because of aortic root dilation, valvulitis, or papillary muscle dysfunction. Recurrent aneurysms and valvular dysfunction can occur despite treatment.¹⁵ Arrhythmias, heart block, and supraventricular tachycardia, caused by myocarditis and involvement of the conduction system occur in rare cases. Frank myocarditis and pericarditis are infrequent.

Ocular symptoms

The eye is a frequent site of involvement. Initially, 19% of patients have eye symptoms, but eventually about 50% are affected. Episcleritis and scleritis can occur at onset or during the course of this disease. Keratitis, thinning

of the cornea, and corneal melt have been reported but are rare. Iridocyclitis, chorioretinitis, retinal hemorrhages, and retinal vasculitis have been observed.⁷ Periocular involvement also occurs and includes periorbital edema, tarsitis, chemosis, proptosis, and palsies of the extraocular muscles.

Renal disease

Although up to 26% of RP patients have abnormal results on urinalysis, the creatinine concentration is elevated in only 10%.¹⁶ In a few patients renal biopsy specimens have shown segmental proliferative glomerulonephritis with crescent formation. Immunoglobulin (IgG or IgM) and the C3 component of complement deposited in a granular pattern, or appearing as subendothelial and mesangial deposits, have been observed on electron microscopy. Renal involvement by an associated autoimmune disease—for example, systemic vasculitis, granulomatosis with polyangiitis (GPA), or systemic lupus erythematosus—has also been observed.

Dermatologic disease

The skin manifestations of RP are variable. They occur as an initial manifestation in 15% of patients, although up to 35% ultimately develop skin involvement. The presence of skin changes does not have any prognostic significance, although such changes appears to occur more commonly in patients who develop RP in association with myelodysplastic syndrome.^{7,17} The presence of palpable purpura, subcutaneous nodules, sterile pustules, urticaria, and angioedema has been observed. Livedo reticularis, migratory superficial thrombophlebitis, erythema nodosum, erythema multiforme, and panniculitis are rare but known. Of course, patients who develop RP in association with another connective tissue disease may manifest skin changes of the underlying illness.

Neurologic disease

Vasculitis involving the central and peripheral nervous system is seen in some patients, who develop cranial neuropathies, headaches, encephalopathy, encephalitis, aseptic meningitis, hemiplegia, and ataxia. Transverse myelitis, mononeuritis multiplex, and temporal artery nongranulomatous vasculitis have been observed.^{18,19}

Miscellaneous features

Fever has been observed in 22% of RP patients at presentation and in up to 44% during the course of the illness. The pattern is variable, and a few patients have had fever of unknown origin. Cases of the coexistence of RP with Behcet syndrome (mouth and genital ulcers with inflamed cartilage [MAGIC] syndrome) have been reported. This interesting presentation of two rare diseases occurring together suggests a shared pathogenic mechanism. Elastin was suggested as a common antigen.²⁰ However, whether this is indeed a bona fide syndrome or simply Behcet syndrome complicated by RP manifestations has been debated in the literature.²¹

DIAGNOSIS AND INVESTIGATIONS

Although the diagnosis of RP is relatively easy, many conditions can mimic the initial changes and an associated disease may confuse the clinical picture. The most commonly used criteria for diagnosis were developed by McAdam and associates²² and require the presence of three or more of the following clinical features to confirm the diagnosis:

- Bilateral auricular chondritis
- Nonerosive seronegative inflammatory polyarthritis
- Nasal chondritis
- Ocular inflammation (conjunctivitis, keratitis, scleritis and/or episcleritis, uveitis)
- Respiratory tract chondritis (laryngeal and/or tracheal cartilages)
- Cochlear and/or vestibular dysfunction (neurosensory hearing loss, tinnitus, and/or vertigo)
- Cartilage biopsy confirmation of a compatible histologic picture

Ear biopsy in auricular chondritis is performed to confirm the diagnosis of relapsing polychondritis (Fig. 167.4). In patients in whom the presentation is characteristic, such as simultaneous chondritis in both auricles or chondritis in multiple sites, a biopsy may not be necessary. If there is early disease, or if another disease ranks high in the differential diagnosis, it may be required.

All patients should be evaluated for laryngotracheal disease because of the potential for serious, life-threatening airway involvement (see Fig.

Fig. 167.4 Biopsy specimen from the ear shows perichondritis with the presence of mononuclear cells and occasional polymorphonuclear leukocytes at the fibrochondral junction (hematoxylin-eosin, $\times 200$). (Courtesy Dr. Lester E. Wold.)

167.3a). Pulmonary function tests, including inspiratory and expiratory flow-volume loops, as well as a radiologic assessment by computed tomography (CT) are both necessary, because either test alone may not reveal the full functional impact of airway disease.¹⁰⁻¹² Laryngotracheal biopsy should be considered with caution because it may lead to acute respiratory distress in patients with stenotic or collapsing airways.

The usual findings on CT of the trachea include wall thickening or luminal collapse caused by edema or granulation tissue (see Fig. 167.3b), fibrosis, and calcification of the tracheal wall. A thickened anterior and lateral tracheal wall with sparing of the posterior noncartilaginous membrane is considered pathognomonic for RP.²³ CT of the chest may also demonstrate flaccidity and dynamic collapse of the airway with expiration (tracheomalacia), as well as bronchial strictures, which lead to air trapping within the lung parenchyma itself. The radiologist should be specifically instructed to obtain CT images during expiration, because over half of RP patients referred for airway imaging have abnormalities only during this phase of the respiratory cycle.²³

In general, there is a good correlation between CT findings and direct visualization of the tracheobronchial tree by bronchoscopy. However, the latter, more invasive procedure should be considered in the evaluation of patients with RP and pulmonary symptoms, because nearly 25% of patients may have additional important findings identified by bronchoscopy. Moreover, in experienced hands, interventional procedures can be performed during bronchoscopy to alleviate airway obstruction.⁸

Renal status should be investigated to exclude the possibility of an accompanying glomerulonephritis.¹⁶ Electrocardiography should be performed to evaluate the cardiac system. In addition, echocardiography may be indicated to evaluate the valves, and CT/magnetic resonance angiography is useful to assess large-vessel involvement. Nonspecific indicators of inflammation are often observed, including an elevated erythrocyte sedimentation rate, anemia of chronic disease, leukocytosis, thrombocytosis, and hypergammaglobulinemia. If a macrocytic anemia is present, the possibility of early myelodysplastic syndrome should be considered.

If RP is observed in the setting of other autoimmune diseases, such as rheumatoid arthritis or other connective tissue diseases, then positive results may be seen on serologic tests such as those for rheumatoid factor and antinuclear antibodies. Complement levels are usually normal in RP but may be low if RP develops in a patient with lupus. The arthritis of RP is usually nonerosive and characterized by juxtaarticular osteopenia and uniform joint space narrowing. However, if RP occurs in a patient with rheumatoid arthritis, the joint damage pattern may mimic that of the latter condition. The presence of antineutrophil cytoplasmic antibodies (ANCA) has been reported in RP. However, because GPA and microscopic polyangiitis are occasionally accompanied by RP, it is possible that this reflects this disease association. Currently, there are no clinically available laboratory markers for ongoing cartilage damage.

DIFFERENTIAL DIAGNOSIS

Although the clinical manifestations of this disease are characteristic, there are circumstances in which the diagnosis may be difficult. The pinna of the ear is exposed and readily injured by trauma, chemicals, or frostbite. The trachea is similarly vulnerable to injury during prolonged endotracheal intubation. Acute streptococcal infection, fungal infection, syphilis, and leprosy all may lead to perichondritis that may be mistaken for RP. Although sparing of the earlobe is characteristic in these cases, sometimes the only

way to make a definite diagnosis is to perform a biopsy. Nasal damage can occur as a result of several different conditions, including drug abuse (e.g., cocaine use), local fungal infections, tuberculosis, syphilis, and leprosy as well as granulomatous lesions such as GPA, lymphomatoid granulomatosis, and lethal midline granuloma. Eye involvement by RP can be difficult to separate from eye involvement by the associated disease. Necrotizing scleritis and keratitis can occur with rheumatoid arthritis, GPA, polyarteritis nodosa, Behçet syndrome, and Cogan syndrome. Other features of these associated diseases may aid in the differential diagnosis. Systemic vasculitis with pulmonary, renal, central nervous system, and other organ involvement can occur. Involvement of the root of the aorta by other diseases should be considered, especially Ehlers-Danlos syndrome, Marfan syndrome, idiopathic medial cystic necrosis, or ankylosing spondylitis.

PATHOGENESIS

Cartilage is an avascular structure made up of chondrocytes, type II collagen, proteoglycan aggregates, and noncollagenous matrix proteins. It is an immunologically privileged site, and thus tolerance does not develop to these antigens. For this reason it is a target of autoimmune responses. RP should be classified as an inflammatory, autoimmune disorder for the following reasons:

1. RP is associated with other well-established autoimmune diseases.
2. RP is associated with the HLA-DR4 allele.²⁴
3. Pathologically, RP lesions show collections of lymphocytes and plasma cells, as well as deposition of immunoglobulin and complement at the fibrocartilaginous junction.²⁵
4. Elevated levels of chemokines, such as monocyte chemotactic protein-1, macrophage inflammatory protein-1 β , and interleukin-8 (IL-8), can be identified in the sera of RP patients and suggest a state of macrophage activation.²⁶
5. Indicators of humoral immune responses to cartilage antigens such as type II collagen and matrilin-1 can be identified in clinical samples from patients with RP.²⁷
6. Immunization of rodents with these same cartilage-derived antigens reproduces the disease.

Research in animal models of this disease has suggested a direct role for an autoimmune response to cartilage components in the pathogenesis of RP. Chondritis can be induced in rats by immunization with native type II collagen.^{28,29} In addition, mice transgenic for either human HLA-DQ8 or both human HLA-DQ6 and HLA-DQ8 develop chondritis and arthritis after type II collagen immunization.^{30,31} Interestingly, the double-transgenic mice develop spontaneous polychondritis, with a relapsing-remitting course, starting at 6 months of age, the mouse equivalent of middle age.³² Chondritis can also be induced in mice by injection of the cartilage matrix protein matrilin-1.³³ This model depends on particular major histocompatibility complex haplotypes, immunoglobulin, and the C5 component of complement connecting adaptive and innate immune responses with disease pathogenesis.^{34,35} Moreover, mice deficient in the antiinflammatory cytokine IL-10 develop more severe matrilin-1-induced chondritis, which implicates this molecule as a suppressor of cartilage inflammation.³⁵ Taken together, these results in rodent models suggest that RP develops when immunologic tolerance to cartilage antigens is broken. The role of enzymatic cartilage destruction is probably just as important, and local release of proteinases and oxygen metabolites may contribute to tissue damage. Whether the immune system initiates a process that is perpetuated by enzymatic damage or whether enzymatic damage exposes privileged antigens that activate the immune system, which thus allows the disease to develop and progress, is not known. Case series reporting that patients with RP and a history of cartilage trauma have more systemic and autoimmune manifestations of their disease suggest that loss of tolerance may be driven by autologous cartilage antigens.³⁶

MANAGEMENT

The initial management of acute RP has been established empirically. In situations of mild auricular and/or nasal chondritis or arthritis, many clinicians initially employ nonsteroidal antiinflammatory drugs or low-dose prednisone. In patients with serious manifestations, such as laryngotracheal

or ocular symptoms, inner ear inflammation, severe auricular or nasal chondritis, systemic vasculitis, aortitis, or glomerulonephritis, prednisone at a dose of 1 mg/kg or higher may be indicated. Our clinical experience suggests that the acute inflammation often responds well, and the corticosteroid dosage can be gradually tapered. However, if relapses occur with dose reduction, patients may require maintenance doses of prednisone and/or a corticosteroid-sparing agent to control their disease.

Strategies for refractory disease or frequent relapses during tapering of the corticosteroid dose are less certain. Because RP is so rare, controlled therapeutic trials have not been performed. The literature is replete with anecdotes of successful therapies ranging from dapsone and colchicine to immunosuppressants and biologic agents. The former two may be useful in milder disease as corticosteroid-sparing agents, whereas immunosuppressants are reserved for those with corticosteroid-refractory or corticosteroid-dependent disease. Azathioprine, cyclophosphamide, chlorambucil, leflunomide, mycophenolate mofetil, and cyclosporine, as well as plasmapheresis and intravenous immunoglobulins, have all been reported to be beneficial.³²⁻³⁴ In cases of recalcitrant RP complicated by tracheal stenosis and malacia, chondritis, and scleritis, successful treatment with biologic agents, including IL-1, IL-6, and tumor necrosis factor antagonists, has recently been described, as reviewed by Kemta Lekpa and colleagues.¹³ This review suggests that most biologics have some efficacy in RP with the exception of rituximab, to which few patients responded. Taken together, these case reports suggest that the therapeutic armamentarium available to the modern rheumatologist can be employed to treat RP. However, the efficacy of these agents in relation to one another and for specific manifestations of RP is unknown. Interestingly, high-dose chemotherapy with autologous stem cell transplantation induced complete remission in one RP patient with chondritis, scleritis, and aortitis for whom treatment with multiple biologic and cytotoxic agents had previously failed.³⁷

Treatment of RP is usually monitored by clinical response. A recent attempt was made to develop a disease activity score for RP that takes into account the various manifestations of RP, but this is still under development and is not widely used.³⁸ Some clinicians recommend annual screening electrocardiograms and pulmonary function tests with flow-volume loops to follow disease over time.³⁹ The erythrocyte sedimentation rate and C-reactive protein level may be useful in some cases if these markers portend a patient's disease activity. Multiple other biomarkers for disease activity have been proposed; however, the role of assays of these biomarkers in monitoring RP in individual patients has not been satisfactorily established.

Laryngotracheal involvement presents special management issues in following the activity of the disease and dealing with the consequences of a structurally impaired airway. Direct laryngoscopy and serial CT of the trachea can be used to monitor disease activity.^{8,23} Bronchoscopic ultrasonographic evaluation has also been described.⁴⁰ Early intervention is recommended for patients with severe focal stenosis or diffuse tracheobronchomalacia.⁴¹ Once flow-limiting airway damage has occurred, tracheostomy is necessary to treat symptomatic subglottic stenosis. Findings from a retrospective case series suggest that tracheal stents may be useful in the management of some patients.⁸ Laser therapy has been described for treatment of laryngeal and endobronchial disease.^{6,41} Nasal continuous positive airway pressure can be tried at night to assist the patient in keeping the airway open while recumbent and asleep. Surgical correction of subglottic stenosis and collapsed nasal cartilage can be performed once the disease is quiescent. Recurrent postobstructive pulmonary infections obviously require antibiotic treatment and respiratory care.

Heart valve replacement and aortic graft surgery have been successful. Surgical failure also has been observed, although such failures likely were due to continued annular inflammation leading to perivalvular leaks as well as recurrent aortitis adjacent to grafts. In a recent large surgical series, postoperative corticosteroid use was associated with valvular complications.⁴² Whether this represents the effect of corticosteroids on wound healing or reflects more severe underlying disease requiring corticosteroid use is not clear. Regardless, immunosuppressive medications should be considered after surgical intervention for the valvular complications of RP in an attempt to limit corticosteroid use and decrease inflammation.⁴²

168 Amyloidosis

■ PHILIP N. HAWKINS

- Amyloidosis is a protein conformational disorder.
- Extracellular accumulation of amyloid fibrils disrupts the structure and function of tissues and organs.
- Amyloidosis can be systemic, affecting tissues throughout the body, or localized to one site or tissue type.
- About 5% of cases of systemic amyloidosis are hereditary.
- Clinical types of amyloidosis are classified according to the amyloid fibril protein.
- A multidisciplinary approach is required for diagnosis and treatment, including genetic and proteomic analysis in many cases.
- Developments in serum biomarkers and imaging, including cardiac magnetic imaging, provide important information for staging disease.
- A number of novel therapies are in development, including specific inhibitors of amyloid formation and immunotherapeutic approaches.

INTRODUCTION

Amyloidosis is a disorder of protein folding in which normally soluble proteins are deposited in the extracellular space as insoluble fibrils that progressively disrupt tissue structure and function. The term *amyloid* is erroneously derived from the Greek word for “starchlike,” and some 30 different unrelated proteins that can form amyloid *in vivo* have now been identified, with clinical amyloidosis classified according to the fibril protein type (Table 168.1). Protein misfolding and aggregation have increasingly been recognized in the pathogenesis of various other diseases, but *amyloidosis*—the disease directly caused by extracellular amyloid deposition—is a precise term for a specific group of disorders.

Amyloid deposition is remarkable in its diversity; it can be systemic or localized, acquired or hereditary, life-threatening or merely an incidental finding. Clinical consequences occur when accumulation of amyloid is substantial enough to disrupt the structure of tissues or organs, leading to impairment of function. The pattern of organ involvement varies within and between types of amyloidosis, but clinical phenotypes overlap greatly. In systemic amyloidosis, virtually any tissue may be involved, and the disease is often fatal, although prognosis has improved as a result of increasingly effective treatments for many of the conditions that underlie it. Greater understanding of the pathogenesis of the disease has also favorably influenced the prognosis by allowing improved diagnosis and clinical characterization, along with the development of rational therapies and better supportive care including hemodialysis and solid organ transplantation. Localized amyloid deposits are confined to a particular organ or tissue and range from being clinically silent through to having serious consequences such as hemorrhage in the respiratory or urogenital tracts, or space-occupying effects. In addition to characterizing the disorders classified as types of amyloidosis, localized amyloid deposition is a hallmark pathologic feature of uncertain significance in various other important diseases including Alzheimer disease, the prion disorders, and type 2 diabetes mellitus, which are beyond the scope of this chapter.

PATHOGENESIS OF AMYLOID

Amyloidosis defies the dogma that the tertiary structure of proteins is determined solely by their amino acid sequence. Amyloid-forming proteins can

adopt two completely different stable structures, with the transformation involving massive refolding of the normal form into one that predominantly comprises a β sheet that can autoaggregate in a highly ordered manner to produce characteristic rigid, nonbranching amyloid fibrils of 10 to 15 nm in diameter and indeterminate length.^{1,2} All amyloid fibrils acquire new biophysical properties including insolubility in physiologic solutions, enhanced resistance to proteolysis, and ability to bind Congo red dye in a spatially ordered manner that produces diagnostic green birefringence under cross-polarized light (Fig. 168.1).

Amyloid deposition occurs in several circumstances:

1. As a consequence of a sustained abnormally high concentration of certain proteins, such as serum amyloid A protein in inflammation and β_2 -microglobulin in renal failure, which underlie susceptibility to AA and $A\beta_2M$ amyloidosis, respectively.
2. In the face of exposure to a normal concentration of a normal but to some extent inherently amyloidogenic protein over a very prolonged period, such as transthyretin in senile amyloidosis.
3. In the presence of an acquired or inherited variant protein with an abnormal and markedly amyloidogenic structure, such as certain monoclonal immunoglobulin light chains in AL amyloidosis and some genetic variants of transthyretin, lysozyme, apolipoprotein AI, and fibrinogen A α chain in hereditary amyloidosis.

The genetic and/or environmental factors that influence individual susceptibility to and the timing of amyloid deposition remain unclear, but once the process has begun, further accumulation of amyloid is unremitting as long as the supply of the respective precursor protein continues. A unifying characteristic of proteins that can form amyloid is that they are relatively unstable. Even under physiologic conditions they can exist in partly unfolded states involving loss of tertiary structure but retention of β -sheet secondary structure, which enables them to autoaggregate into protofilaments and thence into mature amyloid fibrils. Seeding may play a facilitating role, consistent with observations that accumulation of experimentally induced and clinical amyloid can be remarkably rapid following their start.

Composition of amyloid

Amyloid deposits comprise mainly the protein fibrils, but they also contain some common minor constituents, including certain glycosaminoglycans and the normal circulating plasma protein serum amyloid P component (SAP), as well as various other trace proteins such as apolipoprotein E.³ SAP binds in a specific calcium-dependent manner to a ligand expressed by all amyloid fibrils but not their precursor proteins.⁴ This phenomenon is the basis for the use of SAP scintigraphy in some centers for diagnostic imaging and quantitative monitoring of amyloid deposits.⁵ Studies in knockout mice indicate that SAP contributes to amyloidogenesis.

Amyloid fibril-associated glycosaminoglycans mainly consist of heparan and dermatan sulfates. Their universal presence, restricted heterogeneity, and intimate relationship with the fibrils suggest that they may also contribute to the development or stability of amyloid deposits, a possibility supported lately by the inhibitory effect of low-molecular-weight glycosaminoglycan analogues on the experimental induction of AA amyloidosis in mice and disease progression in patients.⁶

Pathologic effects

The pathologic effects of amyloid can largely be attributed to its physical presence. Extensive deposits, which may amount to kilograms, are structurally disruptive and incompatible with normal function, as are strategically

TABLE 168.1
Classification of amyloidosis*

Type	Fibril precursor protein	Clinical syndrome
AA	Serum amyloid A protein	Systemic amyloidosis usually with predominantly renal involvement associated with acquired or hereditary chronic inflammatory diseases. Formerly known as <i>secondary</i> or <i>reactive amyloidosis</i> .
AL	Monoclonal immunoglobulin light chains	Systemic amyloidosis potentially involving many organ systems associated with myeloma, monoclonal gammopathy, and occult B-cell dyscrasias. Formerly known as <i>primary amyloidosis</i> .
ATTR	Normal plasma transthyretin	Senile systemic amyloidosis with predominantly cardiac involvement (senile cardiac amyloidosis).
ATTR	Genetic variants of transthyretin (e.g., ATTR Met30, Ala60, Ile122)	Familial amyloid polyneuropathy (FAP), often with prominent amyloid cardiomyopathy. Predominantly cardiac involvement without neuropathy with certain mutations (e.g., TTR Ile122).
A β_2 M	β_2 -Microglobulin	Dialysis-related amyloidosis (DRA) associated with renal failure and long-term dialysis. Predominantly articular and periarticular involvement.
A β	β -Protein precursor (and rare genetic variants)	Cerebrovascular and intracerebral plaque amyloid in Alzheimer disease. Occasionally familial.
AApoAI	Genetic variants of apolipoprotein AI (e.g., AApoAI Arg26, Arg60)	Autosomal dominant systemic amyloidosis. Predominantly nonneuropathic with prominent visceral involvement, especially nephropathy. Minor wild-type apolipoprotein AI amyloid deposits may occur in the aorta in aging individuals.
AApoAII	Genetic variants of apolipoprotein AII	Autosomal dominant systemic amyloidosis with predominantly renal involvement.
AFib	Genetic variants of fibrinogen A α chain (e.g., AFib Val526)	Autosomal dominant systemic amyloidosis. Nonneuropathic with predominant nephropathy.
ALys	Genetic variants of lysozyme (e.g., ALys His67)	Autosomal dominant systemic amyloidosis. Nonneuropathic with predominantly renal and gastrointestinal involvement. Rarely presents with hepatic rupture.
ACys	Genetic variant of cystatin C (ACys Gln68)	Hereditary cerebral hemorrhage with cerebral and systemic amyloidosis in Icelandic individuals.
AGel	Genetic variants of gelsolin (e.g., AGel Asn187)	Autosomal dominant systemic amyloidosis. Predominantly cranial nerve involvement plus lattice corneal dystrophy. Described and most common in Finland.

*Not exhaustive and amyloid composed of peptide hormones, prion protein, and unknown proteins not included.

Fig. 168.1 Appearance of amyloid in a renal biopsy specimen. (a) Congo red stain revealing amorphous pink material restricted to the glomeruli of a patient with hereditary fibrinogen A α -chain amyloidosis. (b) Same section under high-intensity cross-polarized light showing pathognomonic apple green birefringence.

located smaller deposits, for example, in glomeruli or nerves. It remains possible that amyloid fibrils or prefibrillar aggregates may also be directly cytotoxic in some circumstances, but curiously, amyloid deposits appear to evoke little or no local reaction in the tissues. The relationship between the quantity of amyloid and the degree of associated organ dysfunction differs greatly among individuals and among different organs, and there is a strong impression that the rate of new amyloid deposition may be as important a determinant of progressive organ failure as absolute amyloid load.

Treatments that substantially reduce the supply of amyloidogenic precursor proteins frequently result in the gradual regression of existing amyloid deposits, which is often associated with preservation of or improvement in the function of amyloidotic organs. The natural clearance of amyloid is thought to be mediated by an inefficient macrophage response, which it has lately proved possible to intensify through passive antibody therapies.⁷

ACQUIRED AMYLOIDOSIS

Acquired systemic amyloidosis is known to be the cause of death in about 1 in 1000 people in the United Kingdom, and it may be much underdiagnosed among elderly individuals. The key characteristics of the main subtypes are shown in Table 168.1.

Systemic AL amyloidosis is the most serious and commonly diagnosed type, and referrals of AL amyloidosis to the UK National Amyloidosis Centre

presently outnumber referrals of AA amyloidosis by a factor of 10:1. Although less serious, dialysis related- β_2 M amyloidosis affects about 1 million patients receiving long-term renal replacement therapy worldwide and causes much suffering. Senile ATTR amyloid deposition, predominantly in the heart, occurs in about one quarter of individuals older than age 80 years, but its wider clinical significance is not yet known.

Reactive systemic amyloidosis, AA amyloidosis

AA amyloidosis is a complication of chronic inflammatory disorders, or indeed any condition that gives rise to overproduction of the acute-phase reactant serum amyloid A protein (SAA). The amyloid fibrils are composed of AA protein, an N-terminal fragment of SAA. AA amyloidosis occurs in up to 1% to 5% of patients with rheumatoid arthritis, juvenile idiopathic arthritis, and Crohn disease, and more frequently among those with lifelong autoinflammatory diseases such as familial Mediterranean fever. Most patients have proteinuric renal disease at presentation; liver and gastrointestinal involvement may occur at a later stage, but clinically significant involvement of the heart and nerves is rare.⁸

Pathologic features

The AA fibril protein is a single nonglycosylated polypeptide chain, usually of mass 8000 Da, comprising the 76-residue N-terminal portion of the 104-residue SAA, which is an apolipoprotein of high-density lipoprotein

particles. Most SAA in plasma is produced by hepatocytes under transcriptional regulation by cytokines, especially interleukin-1 (IL-1), IL-6, and tumor necrosis factor. Its circulating concentration can rise from healthy levels of up to 5 mg/L to over 2000 mg/L within 24 to 48 hours of the occurrence of an acute stimulus and can remain persistently high in chronic inflammation.

The AA protein is derived from circulating SAA by proteolytic cleavage, and sustained overproduction of SAA is a prerequisite for AA amyloid formation, but it is not known why it occurs in only some individuals or what initiates its production. In mice, only one of the three major isoforms of murine SAA is a precursor of AA amyloid fibrils. Human SAA isoforms are more complex, but homozygosity for particular types seems to favor susceptibility, although there may also be ethnic influences.

The functions of SAA are not clear, but it serves as an exquisitely sensitive and dynamic acute-phase marker with enormous range. Frequent and long-term monitoring of SAA is vital in the management of all patients with AA amyloidosis, because control of the underlying inflammatory process to substantially reduce SAA production is essential if amyloidosis is to be halted or reversed. Automated immunoassay systems for SAA are available standardized on a World Health Organization international reference standard.

Disease associations

AA amyloidosis occurs in association with chronic inflammatory disorders, chronic local or systemic microbial infections, and occasionally neoplasms, all of remarkable variety. In Western Europe and the United States the most frequent predisposing conditions are idiopathic rheumatic diseases. The lifetime incidence of AA amyloidosis in patients with rheumatoid arthritis and juvenile idiopathic arthritis in Europe is between 1% and 5%, is rather lower in the United States for reasons that are not clear, and is probably decreasing, generally due to improved treatments. Tuberculosis and leprosy are important causes of AA amyloidosis in some areas. Chronic osteomyelitis, bronchiectasis, chronically infected burns and decubitus ulcers, and the chronic pyelonephritis of paraplegia are other well-recognized associations. Hodgkin disease and renal carcinoma, which often cause a major acute-phase response, are the malignancies most commonly associated with systemic AA amyloid. Perhaps surprisingly, up to 10% of patients with AA amyloidosis do not have a clinically obvious chronic inflammatory disease, and these patients are often erroneously assumed to have AL amyloidosis. Although it may remain impossible to identify the of the precipitating acute-phase response in many such patients, the most common identifiable pathologic conditions in such cases in series at the author's own institution have been hitherto undiagnosed inherited periodic fever syndromes⁹ and cytokine-secreting Castleman disease tumors of the solitary plasma cell type, located in either the mediastinum or gut mesentery.¹⁰

Clinical features

The clinical features of AA amyloidosis are dominated by renal involvement, although histologically AA amyloid deposits are distributed widely. More than 90% of patients have nonselective proteinuria due to glomerular deposition at presentation, and nephrotic syndrome may develop before progression to end-stage renal failure.⁸ Hematuria, tubular defects, nephrogenic diabetes insipidus, and diffuse renal calcification occur rarely. Kidney size is usually normal but may be enlarged or, in advanced cases, reduced. End-stage chronic renal failure is the cause of death in 40% to 60% of cases, but acute renal failure may be precipitated by hypotension and/or salt and water depletion following surgery, excessive use of diuretics, or intercurrent infection, and may be associated with renal vein thrombosis. The second most common presentation is with organomegaly, such as hepatosplenomegaly or occasionally thyroid goiter, with or without overt renal abnormality; but in all cases amyloid deposits are widespread at presentation, which is the basis for diagnosis through rectal and other screening biopsies. Histologic involvement of the heart is frequent but rarely results in cardiac failure. Gastrointestinal dysfunction is common in advanced disease, presenting predominantly with diarrhea and occasional bleeding.

AA amyloidosis may present early in the course of an inflammatory disease, but incidence increases over time. The median duration of inflammation before diagnosis of amyloidosis is about 20 years, although it can be as little as 1 year. Prognosis is closely related to the degree of renal dysfunction and the effectiveness of treatment for the underlying inflammatory disorder. In the presence of persistent, uncontrolled inflammation, 50% of patients with AA amyloidosis die within 10 years, whereas if the causative acute-phase response can be persistently suppressed proteinuria can resolve, renal function may be retained, and the prognosis is much better (see treatment section later). Availability of hemodialysis and renal transplantation prevents early death from uremia per se, and despite amyloid deposition in

extrarenal tissues the prognosis is quite similar to that of other causes of end-stage renal failure.¹¹

Amyloidosis associated with immunocyte dyscrasia, AL amyloidosis

Systemic AL amyloidosis, formerly known as *primary amyloidosis*, develops in about 2% of individuals with monoclonal gammopathies.¹² AL fibrils are derived from monoclonal immunoglobulin light chains, which are unique in each patient; this explains the substantial heterogeneity of AL amyloidosis in terms of organ involvement and overall clinical course. Virtually any organ, other than the brain, may be directly affected, but deposition in the kidneys, heart, liver, or peripheral nervous system is most often associated with clinical consequences. Early symptoms are often nonspecific, including marked fatigue. The underlying monoclonal gammopathy is often missed on routine electrophoretic screening with the potential to further delay the diagnosis, which even under favorable circumstances tends to be made at an advanced stage. This emphasizes the need to consider AL amyloidosis as a potential diagnosis in a range of vague clinical presentations and the need for prompt appropriate investigations, such as biopsy of affected organs and sensitive serum free light-chain analysis to identify associated subtle B-cell dyscrasias.¹³

Pathologic features

AL amyloid fibrils are derived from the N-terminal region of monoclonal immunoglobulin light chains and consist of the whole or part of the variable (V_L) domain. The molecular weight of the fibril subunit protein therefore varies between about 8000 and 30,000 Da. Monoclonal light chains are unique to each individual, and the propensity for some to form amyloid fibrils is inherent to their particular structure. Fortunately, only a small proportion of monoclonal light chains are amyloidogenic, but it is not possible to identify these with any certainty from their class or abundance.

The associated B-cell dyscrasias in systemic AL amyloidosis are heterogeneous and include almost any clonal proliferation of differentiated B lymphocytes, including multiple myeloma, Waldenström macroglobulinemia, and occasionally other malignant lymphomas or leukemias. However, well over 80% of cases are associated with low-grade and otherwise "benign" monoclonal gammopathies that are often very subtle.¹⁴ Histologic studies indicate that minor, clinically insignificant amyloid deposits may occur in about 10% of patients with myeloma and in a smaller proportion of patients with monoclonal gammopathy of undetermined significance (MGUS). The cytogenetic abnormalities that commonly occur in multiple myeloma and MGUS, such as 14q translocations and 13q deletion, have also been observed in AL amyloidosis, but their prognostic significance has not been fully elucidated.¹⁵

Systemic AL amyloidosis accounts for about 1 in 1500 deaths in Britain and occurs equally in men and women. The age-adjusted incidence of AL amyloidosis in the United States is estimated to be between 5.1 and 12.8 per million persons per year, which is equivalent to approximately 3000 new cases per year. The median age at presentation is 65 years, but it can sometimes occur in young adults and is probably underdiagnosed in the elderly, in whom monoclonal gammopathies have the highest prevalence.

Clinical features

The clinical features of AL amyloidosis are protean.¹⁴ The heart is affected in 90% of AL patients, in 30% of whom restrictive cardiomyopathy is the presenting feature and in up to 50% of whom it is ultimately fatal. Other cardiac presentations include arrhythmias and angina. Renal AL amyloid has the same manifestations as renal AA amyloid, but the prognosis is worse. Gut involvement may cause motility disturbances (often secondary to autonomic neuropathy), malabsorption, perforation, hemorrhage, or obstruction. Macroglossia occurs rarely but is almost pathognomonic of the AL type (Fig. 168.2). Hypospasmodism sometimes occurs in both AA and AL amyloidosis. Painful sensory polyneuropathy with early loss of pain and temperature sensation followed later by motor deficits is seen in 10% to 20% of cases and carpal tunnel syndrome in 20%. Autonomic neuropathy leading to orthostatic hypotension, impotence, and gastrointestinal disturbances may occur alone or together with the peripheral neuropathy and has a very poor prognosis. Skin involvement takes the form of papules, nodules, and plaques, usually on the face and upper trunk; involvement of dermal blood vessels results in purpura occurring either spontaneously or after minimal trauma and is quite common. Articular amyloid is rare but may superficially mimic acute polyarticular rheumatoid arthritis, or it may present as asymmetrical arthritis affecting the hip or shoulder. Infiltration of the glenohumeral joint and surrounding soft tissues occasionally produces the characteristic "shoulder pad" sign. A rare but serious manifestation of AL

Fig. 168.2 Macroglossia in a patient with AL amyloidosis, with peripheral ridging due to teeth indentation.

amyloid is an acquired bleeding diathesis that may be associated with deficiency of factor X and sometimes also factor IX, or with increased fibrinolysis. It does not occur in AA amyloidosis, although in all types of systemic amyloidosis there may be serious bleeding in the absence of any identifiable factor deficiency due to widespread vascular deposits.

Dialysis-related amyloidosis, β_2 -microglobulin amyloidosis

β_2 -Microglobulin amyloid deposition occurs in patients with dialysis-dependent chronic renal failure and predominantly involves articular and periarticular structures.¹⁶ The amyloid fibril precursor protein is β_2 -microglobulin, which is the invariant chain of the major histocompatibility class I molecule; it is expressed by all nucleated cells and is normally filtered freely at the glomerulus and then reabsorbed and catabolized by the proximal tubular cells. Decreasing renal function causes a proportionate rise in concentration. β_2 -Microglobulin amyloidosis was first described in 1980 and occurs in patients who have been receiving dialysis for several years or, very occasionally, those with longstanding severe chronic renal impairment. Dialysis-related amyloidosis has been recognized mostly in the hemodialysis population, but it also occurs in patients receiving continuous ambulatory peritoneal dialysis. Relatively few patients are maintained on peritoneal dialysis for the 5 to 10 years required for the development of symptomatic β_2 -microglobulin amyloid, but histologic studies of early subclinical deposits suggest that the incidence of dialysis-related amyloidosis is similar among patients treated with the two dialysis modalities.¹⁷ Indeed, β_2 -microglobulin amyloid deposits are present in 20% to 30% of patients within 3 years of commencing dialysis for end-stage renal failure.

Clinical features

The clinical features are largely confined to the locomotor system. Carpal tunnel syndrome is usually the first clinical manifestation of β_2 -microglobulin amyloidosis. Some individuals develop symptoms within 3 to 5 years, and by 20 years the prevalence is almost 100%. Older patients appear to be more susceptible to the disease and tend to exhibit symptoms more rapidly. Amyloid arthropathy tends to occur a little later but eventually affects most patients on dialysis. The arthralgia of β_2 -microglobulin amyloidosis affects the shoulders, knees, wrists, and small joints of the hand and is associated with joint swelling, chronic tenosynovitis, and occasionally hemarthroses. Spondyloarthritis is also recognized, as is cervical cord compression. Deposition of β_2 -microglobulin amyloid within the periarticular bone produces the typical appearances of subchondral erosions and cysts, which can contribute to pathologic fractures, particularly of the femoral neck, cervical vertebrae, and scaphoid.

A hereditary form of β_2 -microglobulin amyloidosis has recently been identified in association with a genetic variant of the protein; it is unrelated to renal failure, and autonomic neuropathy is the predominant clinical manifestation.¹⁸

BOX 168.1 PROTEINS WITH GENETIC MUTATIONS ASSOCIATED WITH AMYLOID DEPOSITION

| ■ Gelsolin | ■ Apolipoprotein AII (very rare) |
| ■ Lysozyme | ■ β_2 -Microglobulin (very rare) |

Senile transthyretin (ATTR) amyloidosis

Microscopic, clinically silent systemic deposits of wild-type senile transthyretin (TTR) amyloid are common in the elderly and involve the heart and blood vessel walls, smooth and striated muscle, fat tissue, renal papillae, and alveolar walls. In contrast to most other forms of systemic amyloidosis, including hereditary TTR amyloidosis caused by mutations in the TTR gene, the spleen and renal glomeruli are rarely affected. The brain is not involved. Clinically, the dominant feature of ATTR amyloidosis is restrictive cardiomyopathy¹⁹; the condition is also often known as *senile systemic* and *senile cardiac amyloidosis*. Deposits in other tissues rarely attain clinical significance besides causing carpal tunnel syndrome in about one fifth of cases, often before cardiac symptoms have developed. About one quarter of patients can be demonstrated to have gastrointestinal amyloid deposits on rectal biopsy. ATTR amyloidosis is rare before age 60, and most patients are at least 70 years of age, with a male preponderance.

A polymorphic variant, TTR Ile122, which occurs in 4% of African Americans, is associated with a syndrome that cannot be distinguished clinically from wild-type ATTR amyloidosis. The penetrance of this variant is not known, but susceptibility to the disease appears to be increased.

Localized AL amyloidosis

Localized deposits of AL amyloid can occur almost anywhere in the body and are consequent on the presence of a focal monoclonal B-cell dyscrasia within the affected tissue, which is itself often hard to demonstrate. Characteristic sites include the skin, airways, conjunctiva, and urogenital tract. The deposits may be nodular or confluent and are associated with a usually inconspicuous focal infiltrate of clonal B-cells producing amyloidogenic light chains. Progression of localized AL amyloid into a truly systemic disease is exceedingly rare, and conservative management is usually appropriate. It is also rare for the focal B-cell dyscrasia to become systemic and to require treatment in its own right.

Localized orbital AL amyloid presents as mass lesions that can disrupt eye movement and the structure of the orbit. Localized laryngeal AL amyloidosis is a well-recognized syndrome that is often amenable to direct or laser excision, but hereditary systemic apolipoprotein AI amyloidosis can also present in this manner. Amyloidosis presenting in the bronchial tree is virtually always localized AL type, as are solitary or multiple amyloid nodules within the lung tissue. If stenotic lesions are accessible, bronchoscopic laser excision can relieve symptoms. In contrast, diffuse alveolar-septal parenchymal deposition is commonly a manifestation of systemic AL amyloidosis. There are anecdotal reports that inhaled steroids may benefit pulmonary symptoms. Breast amyloidosis is associated with Sjögren syndrome in some cases, and MALT lymphoma should be excluded. Lichenoid and macular forms of cutaneous amyloid are distinct and are thought to be derived from keratin or related proteins, whereas nodular cutaneous amyloidosis deposits are generally localized AL type, although the latter can sometimes be a manifestation of systemic AL amyloidosis. Localized urogenital AL deposits are often incidental findings but may present with hematuria or, less commonly, obstruction. They can occur anywhere from the renal collecting system to the urethra, although they are most usually identified within the bladder. Management is conservative or with transurethral laser resection when symptoms occur; cystectomy is rarely required.

HEREDITARY SYSTEMIC AMYLOIDOSIS

Hereditary systemic amyloidosis is caused by deposition of amyloid fibrils derived from genetically variant proteins and is associated with mutations in a number of genes (Box 168.1)

These diseases are all inherited in an autosomal dominant pattern with variable penetrance and present clinically at various times from the teenage years to old age, although usually in mid-adult life. By far the most common hereditary amyloidosis is caused by TTR variants and usually presents as the syndrome of familial amyloid polyneuropathy with peripheral and

autonomic neuropathy. Cystatin C amyloidosis manifests with cerebral amyloid angiopathy with recurrent cerebral hemorrhage and clinically silent systemic deposits, and has been reported only in Icelandic families. Gelsolin amyloidosis presents with cranial neuropathy and is extremely rare. Apolipoprotein AI, lysozyme, and fibrinogen A α -chain amyloidosis present as nonneuropathic systemic amyloidosis that variously affect the major viscera, with renal involvement usually being prominent. Because a family history is quite often absent, these latter conditions are readily misdiagnosed as acquired primary AL amyloidosis and are less rare than previously thought. Indeed, recent routine use of DNA analysis suggests that 5% to 10% of patients with systemic amyloidosis of the non-AA type have hereditary forms of the disease.²⁰ It is imperative that hereditary amyloidosis be identified correctly, because prognosis, treatment, and implications for family members differ substantially from those for acquired amyloidosis.

Familial amyloidotic polyneuropathy, variant transthyretin (ATTR) amyloidosis

Familial amyloidotic polyneuropathy (FAP) is associated with heterozygosity for point mutations in the gene for TTR.²¹ It is an autosomal dominant syndrome with peak onset between the third and seventh decades. More than 100 variant forms of TTR are associated with FAP, and the amyloid fibrils are derived from a mixture of variant and wild-type TTR protein. There are probably several thousand patients with FAP in the world. The disease is characterized by progressive and disabling peripheral and autonomic neuropathy and varying degrees of visceral amyloid involvement, prominently including cardiac amyloidosis, which can be the sole clinical feature in some cases. Deposits within the vitreous of the eye are well recognized and are pathognomonic, whereas deposits in the kidneys, thyroid, spleen, and adrenals are usually asymptomatic. There are well-characterized foci of FAP associated with the most common variant, substitution of methionine for valine at residue 30 (TTR Met30), in Portugal, Japan, and Sweden, but FAP has been reported in most ethnic groups around the world. FAP is most commonly associated with TTR Ala60 in the United Kingdom.²² There is considerable phenotypic variation in the age of onset, rate of progression, involvement of different systems, and disease penetrance generally, even sometimes within a given family. Typically the disease progresses inexorably, causing death within 5 to 15 years.

Some sequence variants of TTR are not associated with amyloidosis, for example TTR Ser6, whereas others, most notably TTR Ile122, are associated with isolated cardiac amyloidosis.

Familial amyloid polyneuropathy with predominant cranial neuropathy

Familial amyloid polyneuropathy with predominant cranial neuropathy is a very rare dominant form of hereditary amyloidosis that presents in mid to late adult life with cranial neuropathy, lattice corneal dystrophy, and a mild distal peripheral neuropathy.²³ It was originally described in Finland but has since been reported in other ethnic groups. There may be skin, renal, and cardiac manifestations, but these are usually covert and life expectancy approaches normal. There is no specific treatment, and the disorder is progressively disfiguring and very distressing in its late stages. The mutant gene responsible encodes a variant form of gelsolin, which is an actin-modulating protein. The functional role of circulating gelsolin is unknown but may be related to clearance of actin filaments released by apoptotic cells.

Nonneuropathic hereditary systemic amyloidosis

Nonneuropathic hereditary systemic amyloidosis is caused by mutations in the genes for lysozyme, apolipoprotein AI and AII, and fibrinogen A α chain. Hitherto thought to be exceedingly rare, it has lately been demonstrated that many affected patients do not have a family history, and up to 5% of patients with systemic amyloidosis have a hereditary nonneuropathic type.²⁰ This has led to routine use of DNA screening at specialist amyloidosis centers.

Hereditary lysozyme systemic amyloidosis has been described in association with seven lysozyme variants, all of which are extremely rare.²⁴ In most patients the disorder manifests in middle age with proteinuria and very slowly progressive renal impairment. There are usually substantial amyloid deposits in the liver, spleen, and upper gastrointestinal tract; dry eyes due to lacrimal gland involvement is an early diagnostic clue. Curiously, in some patients with the least rare His67 variant, the disorder presents in young adulthood with hepatic rupture, whereas in most it presents later on with renal dysfunction. Cutaneous petechial hemorrhage beginning at a young age is a peculiar feature in patients with the Thr56 variant. Many patients experience few symptoms despite having substantial amyloid deposits, but

acute gastrointestinal hemorrhage or perforation is a frequent cause of death.

Apolipoprotein AI is a major constituent of high-density lipoprotein. Twenty amyloidogenic variants are known; of these, 14 are single amino acid substitutions, 4 are deletions, and 2 are deletions-insertions. The resulting clinical syndromes vary but are often associated with substantial amyloid deposits in the liver, spleen, and kidneys. Some mutations are associated with predominant cardiomyopathy and, in the case of the Arg26 variant, an FAP-like syndrome. Several C-terminal variants are associated with hoarseness due to laryngeal amyloid deposits. Other clinical consequences associated with particular mutations include male infertility and skin lesions. The majority of patients eventually develop renal failure, but liver function usually remains well preserved despite extensive hepatic amyloid deposition. Normal wild-type apolipoprotein AI is itself weakly amyloidogenic and is the precursor of small amyloid deposits that occur quite frequently in aortic atherosclerotic plaques.

Hereditary fibrinogen A α -chain amyloid was first identified in a family in 1993; since then, nine further amyloidogenic mutations have been described. These include six single amino acid substitutions, three frameshifting deletion mutations, and a deletion-insertion mutation. By far the most common mutation results in the substitution of valine for glutamic acid at position 526. This type most often presents in the absence of a family history due to low penetrance. Indeed, nearly 5% of patients referred to the UK National Amyloidosis Centre with a presumed diagnosis of acquired AL amyloidosis have hereditary fibrinogen A α -chain amyloidosis. In most patients the disorder presents in late middle age with proteinuria or hypertension and progresses to end-stage renal failure during the following 5 years or so. Amyloid deposition occurs in the kidneys, spleen, and sometimes the liver but is usually asymptomatic in the latter two sites. The majority of patients have an excellent outcome with renal replacement therapy.²⁵

DIAGNOSIS AND INVESTIGATION OF AMYLOIDOSIS

The diagnosis of amyloidosis generally requires histologic confirmation, although the mere demonstration of amyloid deposition does not by itself establish that it is clinically significant. Although amyloidosis does not occur in the absence of amyloid deposits, the latter may be an incidental histologic finding, especially in older individuals. The pathognomonic tinctorial property of amyloid deposits in tissue is apple green-red birefringence when stained with Congo red dye and viewed in intense light through cross-polarized filters. Immunohistochemical staining of amyloidotic tissue sections is the most accessible method for characterizing amyloid fibril protein type (Fig. 168.3), but it does not always produce definitive results, especially in AL type amyloidosis. Amyloid deposits can be quite patchy, and histologic analysis can never provide information about the overall whole-body load or distribution of amyloid deposits, nor does it permit monitoring of the natural history of amyloidosis or its response to treatment. To overcome these problems the author developed radiolabeled human SAP as a specific, noninvasive, quantitative *in-vivo* tracer for amyloid deposits and has used it as a routine tool in clinical practice for 20 years.²⁶ Studies of over 15,000 individuals using scintigraphy and metabolic turnover studies with labeled SAP have contributed greatly to the knowledge of amyloidosis and especially its diagnosis, monitoring, and response to treatment.

Histologic diagnosis of amyloid

The diagnosis of amyloid is most frequently made following biopsy of the kidneys, liver, heart, gut, peripheral nerve, lymph node, skin, thyroid, or bone marrow. When a possible diagnosis of amyloidosis is already being considered, biopsy of subcutaneous fat or rectum is less invasive and results are positive in about 50% to 80% of patients with systemic AA or AL types. Biopsies of affected organs have a higher yield but a greater risk of hemorrhage and other complications.

Congo red stain²⁷ with its resultant green birefringence when viewed with high-intensity polarized light is the pathognomonic histochemical test for amyloidosis,^{27,28} although other fluorochromes and metachromatic stains continue to be used quite widely. Congo red is unstable and must be freshly prepared every 2 months or less. Use of thick sections of 5 to 10 μ m and inclusion in every staining run of a positive control tissue containing modest amounts of amyloid are critical.

Immunohistochemistry is the most accessible method for characterizing the type of amyloidosis, although its success varies with fibril type and it depends on availability of a suitable tissue sample that contains neither too little nor too much amyloid. Antibodies to SAA protein are commercially

Fig. 168.3 Immunohistochemical typing of amyloid deposits. (a) Congo red stain of a renal biopsy specimen showing amyloid deposits in the glomeruli and blood vessels in a patient with rheumatoid arthritis. (b) Immunospesific staining of the amyloid deposits with a monoclonal anti-serum amyloid A protein antibody demonstrating that the amyloid deposits are of AA type.

available and virtually always stain AA deposits, as is the case with antibodies to β_2 -microglobulin in hemodialysis-associated amyloid. In AL amyloid, the deposits in fixed specimens are stained convincingly with antibodies to κ or λ immunoglobulin light chains in only about two thirds of cases, because the technique is hampered by an abundant polyclonal immunoglobulin background and the fact that the light-chain fragments in AL fibrils are chiefly variable domain and unique for each monoclonal protein. Immunohistochemical staining of TTR and other hereditary amyloid fibril proteins may require pretreatment of sections with formic acid, with alkaline guanidine, or by deglycosylation and even then does not always yield definitive results.

Electron microscopy identifies amyloid as straight, rigid, nonbranching fibrils of indeterminate length and 10 to 15 nm in diameter. A diagnosis of amyloidosis made through electron microscopy alone should be regarded with caution because other fibrillar deposition diseases occur. Immunogold staining of amyloidotic biopsy specimens can sometimes be diagnostic of fibril protein type when standard immunohistochemical staining under light microscopy has not produced definitive results.

Problems of histologic diagnosis include inadequacy of tissue samples—for example, the failure to obtain submucosal vessels in a rectal biopsy specimen—and indeed the failure to identify any amyloid in a target organ biopsy specimen never completely excludes the diagnosis. The unavoidable sampling problem means that biopsy cannot reveal the extent or distribution of amyloid generally. Experience with Congo red staining is required if clinically important false-negative and false-positive results are to be avoided. Immunohistochemical staining requires the use of positive and negative controls, including demonstration of specificity of staining by absorption of antisera with the respective antigens.

Nonhistologic investigations

Cardiac amyloid

Myocardial amyloid deposits cause a restrictive type of cardiomyopathy.²⁸ Two-dimensional echocardiography showing small, concentrically thickened ventricles; diastolic dysfunction with or without various degrees of global systolic impairment; dilated atria; homogeneously echogenic valves; and “sparkling” echodensity of ventricular walls is virtually diagnostic of cardiac amyloidosis. However, clinically significant diastolic impairment may be difficult to detect even by comprehensive Doppler ultrasonography and other functional studies, and can sometimes occur in the absence of left ventricular wall thickening. Newer echocardiographic techniques such as strain and strain rate measurements are helpful in demonstrating the typically more pronounced impairment of longitudinal compared with axial contraction. Cardiac magnetic resonance imaging, which reveals various characteristic patterns of late gadolinium enhancement, is emerging as an investigation of great value. Electrocardiography characteristically shows reduced voltages, presumably reflecting replacement of myocardium by amyloid, although this occurs less often in cardiac amyloid of the TTR type than the AL type.²⁹

Localization of certain technetium-labeled bone tracers to amyloidotic hearts has long been described in anecdotal reports, but this phenomenon has lately been revisited and its potential investigated in a systematic fashion. For reasons that remain unclear, technetium-99m diphosphonate and pyrophosphate scintigraphy appear to localize cardiac ATTR amyloid deposits reproducibly and with considerable sensitivity.³⁰

Elevation of serum N-terminal pro-brain natriuretic peptide (NT-proBNP) and cardiac troponin concentrations occur in many types of cardiac dysfunction and in chronic kidney disease. However, significant cardiac AL amyloidosis is excluded by normal values of NT-proBNP.³¹ Cardiac troponin and

NT-proBNP concentrations appear to be powerful predictors of prognosis and survival after chemotherapy in AL amyloidosis. Staging of disease at diagnosis using measurements of these two analytes (the Mayo Clinic staging system) is now in widespread use both in the clinic and in clinical trials.³²

Genomic and proteomic studies

In cases of known or suspected hereditary amyloidosis the gene defect must be characterized. If amyloidotic tissue is available the fibril protein may be identified immunohistochemically and the corresponding gene can then be studied, but when no tissue is available, screening of the genes for known amyloidogenic proteins must be undertaken.

Biochemical and immunochemical analyses for the presence in the plasma of genetically variant amyloidogenic variant proteins also are available, but DNA analysis is the most direct approach. However, it remains essential to corroborate DNA findings by confirming one way or another that the respective protein is indeed the main constituent of the amyloid.

Proteomic analyses of amyloidotic material are increasingly being used in specialist centers, which allows amyloid deposits in ever smaller samples to be characterized.³³

Radiolabeled serum amyloid P component scintigraphy

The universal presence in amyloid deposits of SAP, derived from circulating SAP, is the basis for the use of radioiodine-labeled SAP as a diagnostic tracer in amyloidosis.³ No localization or retention of labeled SAP occurs in healthy subjects or in patients with diseases other than amyloidosis. Radioiodinated SAP has a short 24-hour half-life in the plasma and is rapidly catabolized with complete excretion of the iodinated breakdown products in the urine. However, in patients with amyloidosis, the tracer rapidly and specifically localizes to the deposits in proportion to the quantity of amyloid present and persists there without breakdown or modification. Most experience has been gained with SAP labeled with the pure gamma emitter iodine 123. The associated dose of radioactivity is less than 4 mSv and well within accepted safety limits for diagnostic nuclear medicine imaging. The uptake of tracer into various organs can be precisely and repeatedly quantified.

Important observations regarding amyloid, which have been made for the first time *in vivo* using radiolabeled SAP scintigraphy, include the following: the different distribution of amyloid in different forms of the disease; the presence of amyloid in anatomic sites not available for biopsy (adrenals, spleen); major systemic deposits of forms of amyloid previously thought to be organ limited; a poor correlation between the quantity of amyloid present in a given organ and the level of organ dysfunction; a nonhomogeneous distribution of amyloid within individual organs; and evidence for surprisingly rapid progression and regression of amyloid deposits at different rates in different organs (Fig. 168.4). The long-held belief that amyloid deposition is irreversible and inexorably progressive is evidently incorrect and simply reflects the persistent nature of the conditions that underlie it. Many case reports have described improvement in amyloidotic organ function when underlying conditions have been controlled, which suggests regression of amyloid, and serial SAP scintigraphy provided the means to show that this is indeed the case. Regression of amyloid has been observed when the supply of amyloid fibril precursor proteins has been reduced in AA amyloidosis by vigorous control of rheumatic inflammation, in AL amyloidosis by suppression of the clonal plasma cell disease by cytotoxic drugs, in hemodialysis-associated amyloidosis after renal transplantation, and in hereditary TTR and fibrinogen A α -chain amyloidosis following liver transplantation. It is

Fig. 168.4 Anterior whole-body radiolabeled serum amyloid P component (SAP) scintigraphs demonstrating regression of AL amyloid deposits following chemotherapy. (a) At diagnosis the SAP tracer localized to AL amyloid deposits in the liver, spleen, and bones of this patient, who had hepatomegaly at presentation. (b) A follow-up scan 5 years later following successful chemotherapy shows that there has been regression of amyloid in all sites, most marked in the liver, which has returned to a normal size.

now clear that amyloid deposits exist generally in a state of dynamic turnover, which has encouraging implications for patient management. Labeled SAP studies thus make a valuable contribution to the diagnosis and management of systemic amyloidosis and are performed routinely at the National Health Service National Amyloidosis Centre at the Royal Free Hospital, London.

ASSESSMENT OF ORGAN INVOLVEMENT BY AMYLOID

International consensus criteria for defining organ involvement in systemic amyloidosis were published in 2005 (Table 168.2).³⁴ Organ involvement by amyloid is variously defined clinically, histologically, and according to organ function and through other specialized investigations. Electrocardiography and two-dimensional Doppler echocardiography are the mainstays for assessing cardiac involvement, as are estimates of glomerular filtration and proteinuria for renal involvement. Liver size and serum alkaline phosphatase levels provide simple and accessible, but not overly sensitive, measures of liver involvement. In contrast, amyloid involvement of the gastrointestinal tract, lungs, soft tissues, and nervous system are much less amenable to precise definitions and are even more challenging to monitor quantitatively over time.

NATURAL HISTORY AND PROGNOSTIC FACTORS

Systemic amyloidosis is almost always a progressive disease that, without successful treatment, usually results in death within months to several years. Median survival of patients with AA amyloidosis whose underlying inflammatory disease is not well suppressed is on the order of 5 to 10 years. The prognosis is similar in familial amyloid polyneuropathy but is usually much better in nonneuropathic hereditary types, that is, those associated with mutations in apolipoprotein AI, fibrinogen A α chain, and lysozyme. The prognosis of systemic AL amyloidosis is generally worse than that of AA

TABLE 168.2

Diagnostic criteria for organ involvement by amyloid

Organ	Consensus criteria reported by Gertz and colleagues ³⁴
Heart	Echocardiogram demonstrates a mean wall thickness of >12 mm, no other cardiac cause found
Kidney	Proteinuria of >0.5 g protein per 24 hr, predominantly albumin
Liver	Total liver span of >15 cm in the absence of heart failure, or alkaline phosphatase level of >1.5 times the institutional upper limit of normal
Nerve	Peripheral: clinical; symmetric lower extremity sensorimotor peripheral neuropathy Autonomic: gastric emptying disorder, pseudo-obstruction, voiding dysfunction not related to direct organ infiltration
Gastrointestinal tract	Direct biopsy verification with symptoms
Lung	Direct biopsy verification with symptoms Interstitial radiographic pattern
Soft tissue	Tongue enlargement, clinical Arthropathy Claudication, presumed vascular amyloid Skin Myopathy by biopsy or pseudohypertrophy Lymph node (may be localized) Carpal tunnel syndrome

From Gertz MA, Comenzo R, Falk RH, et al. Definition of organ involvement and treatment response in immunoglobulin light chain amyloidosis (AL): a consensus opinion from the 10th International Symposium on Amyloid and Amyloidosis. Am J Hematol 2005;79:319-28.

and hereditary types, and median survival in some quite recent series was only 12 to 15 months.³⁵ Important factors that influence prognosis are the extent and severity of organ involvement, the availability of supportive measures including renal dialysis and organ transplantation, and the potential for and effectiveness of reducing the supply of the respective amyloid fibril precursor protein through intervention.

Systemic AL amyloidosis not only is the most common type but also is the most heterogeneous in its organ involvement, presentation, and clinical course. Half of deaths are due to cardiac involvement, and in patients in whom heart failure is evident at presentation, median survival is 6 months. There has been much recent effort to define prognostic factors in AL amyloidosis, and staging systems are in development. Symptomatic or substantial echocardiographic evidence of cardiac amyloid is associated with an expected survival of only 6 to 12 months. Patients with liver involvement and hyperbilirubinemia with bilirubin levels above 35 μ mol/L rarely survive longer than 4 months. Significant autonomic neuropathy, progressive clonal disease unresponsive to chemotherapy, and a bone marrow plasmacytosis of over 20% are also associated with poor outcomes. A large whole-body amyloid load as determined by SAP scintigraphy and evidence of accumulation of amyloid on follow-up SAP scans are further poor prognostic features. Prognosis is better when proteinuria or peripheral neuropathy is the dominant clinical feature or there is substantial suppression of underlying clonal disease by chemotherapy and regression of amyloid deposits on serial SAP scintigraphy. Elevated serum concentrations at diagnosis of the cardiac biomarkers troponin and BNP or its more stable precursor, NT-proBNP, are associated with a poor outcome, as is the absence of an early fall in their concentrations following chemotherapy.³⁶

TREATMENT OF AMYLOIDOSIS

The twin aims of management in systemic amyloidosis are reduction of the supply of amyloid fibril precursor proteins so that amyloid deposition diminishes and gradual regression of existing deposits may occur, and scrupulous general care, including dialysis and organ transplantation if necessary, to keep patients alive long enough for this to occur. Awareness of the compromised functional reserve of amyloidotic organs and extreme care to protect renal function are critically important. Rational management has been greatly facilitated by the recent availability of routine assays for circulating SAA in AA amyloidosis and serum free light chains in the AL type, and outcomes are much better in centers with specialist expertise.

Treatment of AA amyloidosis

Treatment of the chronic inflammatory conditions underlying AA amyloidosis, ideally to reduce serum SAA concentration to normal healthy levels, inhibits amyloid deposition, frequently leads to regression of deposits, and dramatically improves survival. Plainly, treatment varies depending on the nature of the inflammatory disorder, and successful pharmacologic approaches have ranged from nonspecific immunosuppression in inflammatory arthritis³⁷ to highly specific inhibition of IL-1 in patients with periodic fever syndromes.³⁸ Inflammatory arthritis underlies AA amyloidosis in two thirds of cases, and biologic agents targeting the key cytokine mediators of inflammation—tumor necrosis factor- α , IL-1, and IL-6—potently suppress the acute-phase response in many patients with rheumatoid arthritis, juvenile idiopathic arthritis, and seronegative spondyloarthritis. These drugs can also be effective in some patients with Crohn disease. Regular prophylactic treatment with colchicine is highly effective in suppressing familial Mediterranean fever and almost completely prevents the development of AA amyloidosis.

Localized amyloid masses can only be treated surgically. Surgical treatments include excision of solitary cytokine-secreting Castleman tumors and amputation of osteomyelitic limbs, and rarely excision of other inflammatory lesions.

A surprising finding among patients with AA amyloidosis is that of clinically covert inflammatory disease, which cannot be characterized, in up to 10% of patients. Many such patients are presumed to have primary AL amyloidosis at presentation, which emphasizes the need to perform confirmatory immunohistochemical testing in all cases. Antiinflammatory treatment must be empiric in such cases but, as is the case in all patients with AA amyloidosis, should be guided by frequent SAA measurements.⁸

Treatment of AL amyloidosis

The objective of treatment in AL amyloidosis is to suppress production of amyloidogenic monoclonal light chains in the hope that progression of the disease will be slowed down, halted, or reversed.³⁹ However, many patients have advanced multisystem disease at diagnosis and tolerate chemotherapy poorly. Quantitative measurements of serum free light chains using the robust, sensitive Freelite immunoassay are usually the most effective means of evaluating the early effects of chemotherapy and the need for ongoing treatment.⁴⁰ Chemotherapy must be tailored to the individual patient to achieve a balance between the ideal of complete remission of the underlying clonal disease and the need to minimize treatment-related toxicity and mortality. Certain organs affected by amyloid tend to fare better than others following treatment. Proteinuria and liver function often gradually improve when the clonal disease is adequately suppressed, whereas macroglossia and peripheral nerve function tend to improve extremely slowly if at all.

Many different chemotherapy regimens are in current use, ranging from oral cyclic combinations to high-dose chemotherapy with autologous peripheral stem cell rescue.⁴¹ The new agents bortezomib^{42,43} and lenalidomide,⁴⁴⁻⁴⁶ recently introduced for treatment of myeloma, are also showing great promise in AL.

Treatment of hereditary amyloidosis and organ transplantation

At present, other than transplantation to replace failed organs and, in certain cases, liver transplantation to remove the source of amyloidogenic proteins of hepatic origin, treatment of hereditary systemic amyloidosis is limited to management of symptoms. The liver is the source of plasma TTR, and over 2000 liver transplantations have been performed for treatment of hereditary ATTR amyloidosis since this “surgical gene therapy” approach was introduced in 1991. In younger patients carrying the common TTR Met30 amyloidogenic mutation the outcome is relatively good, with arrest or slowing

of progression of neuropathy and regression of visceral amyloid, but vitreous amyloid deposition may subsequently progress because some TTR is also produced within the eye. Cardiac amyloidosis present at the time of liver transplantation also usually progresses due to accumulation of wild-type TTR on the existing myocardial deposits, which excludes its applicability to the majority of patients with non-Met30 mutations. The livers of patients with hereditary TTR amyloidosis contain only microscopic amyloid deposits in the blood vessels and interstitial tissues, and normal liver function is retained. A large number of domino liver transplantations have therefore been conducted in recipients with various terminal liver diseases for whom normal livers were not available. This has certainly prolonged the lives of these patients, but several recipients have developed iatrogenic symptomatic systemic ATTR amyloidosis less than 10 years after transplantation.

Kidney and very occasionally liver transplantation is the mainstay of treatment in patients with fibrinogen A α -chain and apolipoprotein AI amyloidosis.

Supportive treatment

Supportive therapies remain a critical component of the management of amyloidosis. For cardiac amyloidosis, the mainstay of treatment is diuretics coupled with fluid restriction, daily weighing, and a low-salt diet, whereas the role of vasodilating drugs and β -blockers is unclear. Refractory edema may respond well to the addition of spironolactone and intermittent doses of metolazone. Salt-poor albumin infusions can also occasionally be helpful. Dysrhythmias may respond to drugs or to device implantation. In renal amyloidosis, rigorous control of hypertension is vital, and angiotensin-converting enzyme inhibition and/or angiotensin II blockade is often recommended when proteinuria is present. Renal dialysis may be necessary and is usually both feasible and acceptably tolerated. In autonomic neuropathy, fludrocortisone 100 to 200 μ g/day can be helpful in some patients but may simply exacerbate fluid retention. Midodrine is an effective pressor agent, starting at a dose of 2.5 mg and building up to 15 mg thrice daily. Midodrine exerts its actions via activation of the α -adrenergic receptors of the arteriolar and venous vasculature, producing an increase in vascular tone and elevation of blood pressure. Gastroparesis causing symptoms of early satiety and nausea can be managed with prokinetic agents such as metoclopramide, along with advice to consume small, frequent meals of soft foods. Diarrhea due to amyloid gut involvement or autonomic neuropathy may respond to loperamide and codeine phosphate. Malnutrition is common and is often underestimated.⁴⁷ Significant weight loss should be treated with protein and vitamin supplementation, and the patient should be evaluated by an experienced dietitian. Feeding via gastrostomy may occasionally be required. Amyloid and chemotherapy-related peripheral neuropathy can be disabling and difficult to treat. For analgesia, opioids and nonsteroidal antiinflammatory drugs, amitriptyline, venlafaxine, anti-epileptics, transcutaneous electrical nerve stimulation, and/or gabapentin/pregabalin have all been used, although anecdotal reports suggest variable and limited efficacy. Withdrawal or dose reduction of any neurotoxic chemotherapeutic agents such as thalidomide or bortezomib often needs to be considered.

New treatments and future directions

Elucidation of aspects of the molecular pathogenesis of amyloid and amyloidosis has led to the development of various novel approaches to therapy. These include agents that stabilize and maintain circulating amyloid precursor proteins in their normal conformation,⁴⁸ agents that inhibit the interaction between amyloid fibrils and glycosaminoglycans, immunotherapy approaches,⁴⁹ depletion of SAP,⁵⁰ and silencing RNA and antisense oligonucleotide therapies. All of these potential new therapies have entered clinical testing, which offers real promise that specific anti-amyloid therapies may become available within the next few years.

Digital clubbing and hypertrophic osteoarthropathy

■ MANUEL MARTÍNEZ-LAVÍN ■ CARLOS PINEDA

- Hypertrophic osteoarthropathy is a syndrome characterized by abnormal proliferation of the skin and osseous tissues at the distal parts of the extremities.
- Three features are typically present: a peculiar bulbous deformity of the tips of the digits conventionally described as *clubbing*, periostosis of the tubular bones, and synovial effusions.

HISTORY

Digital clubbing is one of the oldest clinical signs in medicine. Its original recognition has been attributed to Hippocrates (circa 450 BC).¹ Marie, in 1890,² and Bamberger, in 1891,³ described the fully developed syndrome. Marie distinguished it from acromegaly and suggested the term *pulmonary hypertrophic osteoarthropathy*. Because the site of primary disease may be in areas other than the lungs, this designation fell into disuse. The term used today is *hypertrophic osteoarthropathy* (HOA). Paleopathologic studies have demonstrated changes consistent with HOA in human skeletal remains from pre-Hispanic Mesoamerica.¹

EPIDEMIOLOGY

There are no systematic studies of the prevalence of digital clubbing in either the general population or hospital inpatients. The deformity is associated with a variety of internal illnesses, so that most clinicians, regardless of their specialty, have frequent encounters with patients who display this abnormality.

The veterinary literature contains reports of this illness in different species of mammals, in which the syndrome appears in response to the same illnesses as those reported for humans. HOA has been artificially produced in dogs by surgically caused right-to-left shunts of blood or by chemically induced lung cancer. Nevertheless, a stable animal model of the syndrome, accessible for systematic studies, has not been developed.

CLASSIFICATION

The classification of HOA is outlined in Figure 169.1. There is now evidence to support the contention that clubbing and HOA represent different stages of the same disease process.⁴ In the overwhelming majority of cases, the finger deformity is the first manifestation, and as the syndrome progresses, periostosis becomes evident. The degree of association of clubbing with the diverse illnesses varies, with clubbing ranging from being a constant finding, as in cases of cyanotic heart diseases, to being a rare manifestation, as in patients with cancer of the lung, liver cirrhosis, or Graves disease.

Synonyms for the deformity besides clubbing include *drumstick*, *pendulum*, and *hippocratic fingers*. Primary HOA is also known as *pachydermoperiostosis*. The term *acropachy* is etymologically the most appropriate and has been used to describe either clubbing or the fully developed syndrome.

CLINICAL FEATURES

In HOA there is a spectrum of symptoms. At one extreme, patients may be asymptomatic and unaware of the deformity of their digits. Other patients, in particular those with malignant lung tumors, may notice a burning sensation of the fingertips and may also experience incapacitating bone pain.

Characteristically, this pain is deep-seated, more prominent in the lower extremities, and aggravated by dependency of the limbs.

Physical examination is of foremost importance in diagnosis, because the bulbous deformity of the fingertips is unique (Fig. 169.2). The nail becomes convex (watch-crystal nail), and the skin overlying its base becomes thin and shiny, with disappearance of the normal creases. The edema and increased soft tissue produce rocking of the nail bed on palpation. Toes are also affected, but early changes are more difficult to discern here because of the splaying of the normal toe tip.

The Digital Index provides a practical method to measure clubbing (Fig. 169.3). With the use of a nonelastic string, the perimeter of each finger is measured at the distal interphalangeal joint and at the nail bed. If the sum of the 10 ratios of nail bed to distal interphalangeal joint is more than 10, clubbing is probably present. There is variation in the prominence of clubbing, and the Digital Index serves to assess the severity of the deformity or to compare groups of patients or responses to treatment.⁵ The most advanced stages, with a Digital Index greater than 11, are seen predominantly in patients with cyanotic heart diseases or primary HOA.

It is worth noting that, in the majority of cases, clubbing is the only manifestation of the syndrome. When all features of HOA are present, however, skin hypertrophy may be evident at other levels, with coarsening of the facial features or nonpitting cylindrical soft tissue swelling at the ankles ("elephant legs"). Thickening of the tubular bones may be evident in areas of the extremities not covered by muscles, such as the ankles and wrists.

Periostosis may be accompanied by tenderness on palpation of the involved area but in some instances is asymptomatic. Effusions into the large joints are frequently observed and are more easily detected in the knees and wrists. At the ankle they are more difficult to detect because of the surrounding soft tissue swelling. On palpation there is no hypertrophy of the synovial membrane. The range of motion of the joints may be slightly decreased. Arthrocentesis yields a very thick fluid with a tendency to spontaneous clotting. There is little inflammatory cell exudation, and the white blood cell count is usually less than 500/mm³ in the synovial fluid.⁶ All these features reflect the fact that HOA is not a proliferative synovial disease. Effusions are most likely a sympathetic reaction to the nearby periostosis.

There are other clinical findings associated with particular types of HOA that echo the involvement of an internal organ. Cyanosis is prominent in heart malformations associated with right-to-left shunts of blood. These patients present the prototype of HOA, because almost all have lifelong presence of clubbing and more than 33% display the fully developed syndrome.⁷ No other internal illness is so closely associated with HOA. A lesser degree of cyanosis is seen when the acropachy is associated with cystic fibrosis, pulmonary fibrosis, or chronic infections. Jaundice, ascites, and palmar erythema are common findings when the syndrome is secondary to liver cirrhosis. Chronic diarrhea is a constant finding in intestinal HOA.

Thyroid acropachy is a rare manifestation of Graves disease and is independent of the state of thyroid function. Clubbing usually coexists with exophthalmos and pretibial myxedema. The myxedema bears a resemblance to the elephant legs described in other types of HOA. Thyroid acropachy is characterized by an exuberant periosteal proliferation, located mostly at the small tubular bones of the hands and feet.⁸ Patients with POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal proteins, and skin changes) often display features of HOA, such as digital clubbing, skin thickening, and hyperhidrosis.⁹

Forms of HOA localized to one or two limbs may be seen. Most of these occur as a result of a prominent endothelial injury of that particular limb, such as in cases of arterial aneurysms or endothelial infections. A growing number of cases of localized HOA secondary to infection of an arterial graft have been reported. These are characterized by painful swelling of the

Fig. 169.1 Various forms of hypertrophic osteoarthropathy. AV, arteriovenous; POEMS, polyneuropathy, organomegaly, endocrinopathy, monoclonal proteins, and skin changes.

Fig. 169.2 Clubbing deformity. The finger on the right is clubbed compared with the normal-shaped finger on the left.

Fig. 169.3 Method of determining the Digital Index. The perimeter of each of the 10 fingers is measured at the nail bed (NB) and at the distal interphalangeal joint (DIP). If the sum of the 10 NB-DIP ratios is more than 10, clubbing is probably present.

Fig. 169.4 Hypertrophic osteoarthropathy. Wrist radiograph shows periostitis at the distal ends of the radius and ulna. The coarse, layered appearance is most evident along the diaphyses. The relative sparing of the radial epiphyses is characteristic.

affected limb associated with radiographic periostitis; clubbing has been reported in a minority of such cases.¹⁰ Another form of localized HOA is secondary to patent ductus arteriosus complicated by pulmonary hypertension. In these instances, clubbing and sometimes periostitis are limited to the cyanotic limbs.¹¹

Primary HOA is characterized by a clear-cut hereditary predisposition, with 33% of patients having a close relative with the same illness. The male-female ratio is 9:1. Primary cases are prone to display a more disseminated skin hypertrophy, hence the term *pachydermoperiostosis*.¹² This overgrowth roughens the facial features and can reach the extreme of cutis verticis gyrata, the most advanced stage of cutaneous hypertrophy. In such cases, the scalp takes on a cerebroid appearance. Another cutaneous alteration more frequently seen in idiopathic cases is glandular dysfunction, manifested as hyperhidrosis, seborrhea, or acne, or combinations thereof. A variety of associated abnormalities have been described in primary HOA: cranial suture defects, males with female escutcheon, and hypertrophic gastropathy.¹³ In primary HOA, the activity of the illness is usually limited to the growth period, with adults becoming asymptomatic. There are cases

of primary HOA that show an enigmatic clinical palindrome. Such cases display, as late manifestations, diseases that in other circumstances are known causes of HOA. In this palindrome, persistent ductus arteriosus, Crohn disease, or myelofibrosis can be the cause or the effect of HOA.¹⁴

INVESTIGATIONS

At the present time there are no useful serologic tests for HOA. An array of biochemical abnormalities may be found, however, reflecting the underlying illness.

Of utmost importance for the correct assessment of HOA are plain radiographs of the extremities, which may reveal abnormalities in an asymptomatic patient: long-standing clubbing is characterized by a bone-remodeling process that usually takes the form of acro-osteolysis (Fig. 169.4) and, more rarely, tuftal overgrowth (Fig. 169.5). Characteristically, the bone changes of clubbing are observed first at the toes; fingers are affected in more advanced cases.¹⁵ Periostitis is an orderly, evolutionary process that depends

Fig. 169.5 Clubbing and hypertrophic changes. Anteroposterior view of the foot of a 34-year-old man with primary hypertrophic osteoarthropathy demonstrates marked clubbing and hypertrophic changes, with "mushrooming" of the tufts.

Fig. 169.6 Monolayer periostosis. Typical location of the early periosteal changes of hypertrophic osteoarthropathy. A monolayer type of periostosis is seen in this anteroposterior view of the ankle of a 20-year-old woman with tetralogy of Fallot.

on the chronicity of the illness and the intensity of the underlying stimuli. It progresses in three dimensions: in the number of affected bones, in the site of involvement of a given bone, and in the shape of the periosteal apposition. In mild cases, few bones are affected (usually tibiae and fibulae); periostosis is limited to the diaphysis and has a monolayer configuration (Fig. 169.6). In advanced cases, all tubular bones are affected; in addition to the diaphysis, the metaphysis and epiphysis are also involved, and the periostosis takes on an irregular configuration (see Fig. 169.4).

Periostosis has a symmetric distribution and evolves in a centripetal fashion. It is independent of the underlying illness; primary and secondary cases feature similar changes.¹⁵ Typical of HOA is preservation of joint space and the absence of erosions or para-articular osteopenia.

Radionuclide bone scanning is a sensitive method for demonstrating periosteal involvement. There is hyperconcentration of the bone-seeking tracer at the periosteum. When this technique is used, the diagnosis of HOA is sometimes made serendipitously in patients with known malignant disease who have developed bone pain, with the study being requested for the evaluation of metastatic cancer.

DIFFERENTIAL DIAGNOSIS

When HOA is fully expressed, the drumstick fingers are so unique that its recognition poses no dilemma. Nonetheless, there are borderline cases in which neither a careful examination nor the Digital Index clarifies the situation. The most appropriate approach for such cases is to assume the presence of clubbing and to search for an underlying illness.

Diagnostic criteria for HOA are the combined presence of clubbing and radiographic evidence of periostosis of the tubular bones. The presence of synovial effusion is not essential for the diagnosis.¹⁶ Nevertheless, it should be emphasized that in some patients, particularly those with malignant lung tumors, painful arthropathy may be the presenting manifestation of the syndrome, in advance of clubbing. Such patients could be misdiagnosed as having an inflammatory type of arthritis.¹⁷ Here, important clinical features in the differential diagnosis are the location of pain (in HOA not only the joint but also the adjacent bone is involved) plus the fact that rheumatoid factor is usually absent and synovial fluid is noninflammatory.

Some patients with HOA have an exuberant skin hypertrophy that may resemble acromegaly. The presence of clubbing and periostosis plus the absence of prognathism, enlarged sella turcica, or abnormal circulating concentrations of growth hormone should lead to the correct diagnosis. A patient should be classified as having the primary form of the syndrome only after careful scrutiny fails to reveal an underlying illness.

Several cases of painful multifocal nodular periostitis have been described recently in transplant recipients taking voriconazole. Voriconazole is a new fluoride-containing antifungal medication. Fluorosis appears to be the underlying pathogenetic factor. Symptoms subsided after medication withdrawal.¹⁸

The importance of recognizing HOA cannot be overstated. If, in a previously healthy individual, any of the manifestations of the syndrome become evident, a thorough search for an underlying illness should be undertaken. Special attention must be directed to the chest, because nowadays the most frequent cause of an acute onset of HOA in adults is malignant lung tumor, either primary or metastatic. Conversely, if a patient previously diagnosed with any of the chronic illnesses outlined in Figure 169.1 develops clubbing, this alone is an unfavorable prognostic sign, indicating that the disease has reached an advanced stage.

In some clinical situations, the presence of acropachy signals a serious but treatable complication. If clubbing appears in a patient with known rheumatic heart disease, infective endocarditis should be strongly suspected. A similar consideration applies to patients with a history of prosthetic vascular surgery who develop periostosis of a limb.

STRUCTURE

The bulbous deformity of the digits is secondary to excessive laying down of collagen fibers and interstitial edema. There is also vascular hyperplasia and thickening of the vessel walls, with a perivascular infiltrate of lymphocytes.

Electron microscopic studies have confirmed the structural vessel damage by demonstrating the presence of Weibel-Palade bodies and the prominence of Golgi complexes.¹⁹ Similar changes have been observed in the bones. At this level, excessive connective tissue elevates the periosteum and new osteoid matrix is deposited beneath.

Histologic studies of the joints have found minimal synovial cell proliferation but a prominent artery wall thickening, with intravascular deposition of electron-dense material.⁷

ETIOLOGY AND PATHOGENESIS

Significant advances in the understanding of HOA have been made in recent decades.¹⁸ Any valid theory attempting to unravel its pathogenesis must explain the peculiarities of the syndrome, namely, how such different illnesses can induce so unique a deformity. It must also explain the reason for the acropachy—why the syndrome begins at the most distal parts of the extremities, evolving in a centripetal fashion. Lastly, it must also account for the pathologic features of edema, localized endothelial hyperplasia, and excessive collagen deposition. Several hypotheses that have been proposed to explain these peculiarities are now supported by experimental data.^{5,20,21}

The majority of illnesses associated with HOA have, in common, alteration of lung function. Such an alteration may be the result of exclusion of this organ from part of the circulation, a phenomenon evident in cyanotic heart diseases but also present to a lesser degree in some cases of cancer of

the lung, intestinal polyposis, or the hepatopulmonary syndrome of liver cirrhosis. In the last condition there is an “intrapulmonary” shunting of blood.²² A particularly strong argument in favor of the key role of lung bypass in the development of HOA is the existence of patients with patent ductus arteriosus complicated by pulmonary hypertension in whom the acropachy is limited to the cyanotic limbs.¹¹ Another form of alteration of lung function results from a direct injury to the lung parenchyma from an assortment of diffuse interstitial illnesses listed in Figure 169.1.

The lack of inflammatory and autoimmune phenomena by conventional serologic testing, in addition to the excessive collagen deposition evident in histologic studies, led to a proposal that a fibroblast growth factor could be at the epicenter of the syndrome.⁴ This factor would normally be present in the central venous circulation and removed in the lung. A platelet-derived growth factor was chosen on the basis of a mathematical model, which suggested that, in normal circumstances, large platelets are fragmented in the pulmonary circulation. It was suggested that, in patients with right-to-left shunts of blood, large thrombocytes that escaped fragmentation in the lung enter the systemic circulation and reach its most distal parts on axial streams, there releasing growth factors and inducing acropachy.²¹

Studies of patients with HOA associated with cyanotic heart diseases have yielded data consistent with these explanations. It has been found that these patients have a bizarre platelet population, characterized by the presence of macrothrombocytes with aberrant volume-distribution curves.²³ Such cyanotic patients also display alterations in another distal part of the circulation—the renal glomeruli. Histologic studies have disclosed glomerular enlargement, with trapped megakaryocyte nuclei inside.²⁴ These features are consistent with the theory of platelet fragmentation in the lung. Furthermore, it has also been demonstrated that these cyanotic patients, and patients with primary HOA, have increased circulating concentrations of von Willebrand factor antigen, an abnormality that reflects activation of the platelet/endothelial cell.²⁵ There are theoretical grounds to suggest that similar mechanisms may be operative in other illnesses associated with acropachy. Endothelial cell activation is a prominent feature of endarteritis and endocarditis of infective origin.

These data suggest that localized activation of the platelet/endothelial cells, with the subsequent release of growth factor(s), has a key role in the development of HOA (Fig. 169.7). Recent evidence suggests that vascular endothelial growth factor (VEGF) may play a key role in the pathogenesis of HOA. VEGF is one of the platelet-derived growth factors released during platelet/endothelial cell activation. It is also produced by malignant tumors as a mechanism of cancer growth. Furthermore, VEGF is a hypoxia-induced agent. These peculiarities may explain how different hypoxic and malignant illnesses may induce VEGF overexpression. Moreover, VEGF induces vascular hyperplasia, new bone formation, and edema, which are precisely HOA histologic abnormalities. These theoretical considerations are now supported by experimental data. Plasma and serum concentrations of VEGF are significantly higher in patients with primary HOA and with HOA associated with lung cancer than in normal control subjects.²⁶ Histologic analysis has shown that VEGF is overexpressed in the stroma of clubbed digits.²⁷

Recent genomic evidence proposes that prostaglandins may play a key role in the pathogenesis of HOA. Study of several families with primary HOA disclosed a mutation in the 15-hydroxyprostaglandin dehydrogenase gene. Affected individuals had chronically elevated prostaglandin E₂ levels.²⁸ It seems unlikely, however, that prostaglandins could play a direct final role in the pathogenesis of HOA. No evidence exists that the skeletal syndrome regresses with the use of nonsteroidal antiinflammatory drugs. These drugs are potent prostaglandin inhibitors. Rather, prostaglandin E₂ may act as facilitator of VEGF action on osteoblasts. It has been shown that the action

Fig. 169.7 Theoretic explanation for the development of hypertrophic osteoarthropathy (HOA). Megakaryocytes emerge from the bone marrow and, in normal circumstances, are fragmented in the lung microvasculature. In individuals with cyanotic heart disease (in this case, tetralogy of Fallot), the large fragments would not enter the pulmonary circulation; instead, they would directly enter the systemic circulation, reach its most distal sites, release growth factors, activate endothelial cells, and thus induce finger clubbing. In individuals with lung cancer, a growth factor derived from abnormal tissue would enter the systemic circulation and induce clubbing.

of prostaglandins on bones is mediated precisely through VEGF expression.²⁰ It is clear that more research is needed to elucidate the pathogenesis of HOA.

MANAGEMENT

Apart from its unsightliness, clubbing is usually asymptomatic and does not require treatment. For patients with painful osteoarthropathy, nonsteroidal antiinflammatory drugs are effective in alleviating pain in most cases. There are isolated case reports from different parts of the world stating that intravenous infusions of bisphosphonates are effective in HOA patients with refractory bone pain.²⁹ Bisphosphonates are not only osteoclastic bone resorption antagonists but also VEGF inhibitors.

Removal of a lung tumor, correction of a heart malformation, or successful treatment of infective endocarditis is followed by a dramatic regression of all features of the syndrome.

Miscellaneous arthropathies

■ JONATHAN KAY ■ THOMAS BARDIN

- Localized arthritis can be caused by metastatic disease, cartilaginous tumors, foreign body synovitis, synovial osteochondromatosis, pigmented villonodular synovitis, synovial sarcomas, and palindromic rheumatism.
- Polyarthritis can be caused by carcinomatous polyarthritis, bypass arthritis, hypertrophic osteoarthropathy, intermittent hydrarthrosis, multicentric reticulohistiocytosis, SAPHO syndrome (synovitis, acne, pustulosis, hyperostosis, and osteitis), and Whipple disease.
- Systemic syndromes can be associated with angioimmunoblastic T-cell lymphoma, Castleman disease, and leukemia.
- Musculoskeletal complications of chronic kidney disease are frequently faced by clinicians caring for these patients; apatite (basic calcium phosphate) disease is the most common.
- Nephrogenic systemic fibrosis is a debilitating fibrosing condition affecting patients with chronic kidney disease after exposure to gadolinium-containing contrast agents during magnetic resonance imaging.
- Medications used to manage musculoskeletal conditions, such as colchicine and allopurinol, require significant scrutiny and dose adjustment in the context of dialysis and renal transplantation.

CANCER-RELATED MUSCULOSKELETAL SYNDROMES

When the relationship between cancer and musculoskeletal disease is reviewed, it is helpful to consider three major aspects: (1) the association of several rheumatologic disorders with an increased risk of malignancy; (2) musculoskeletal manifestations of cancer, including metastatic disease; and (3) malignancies that may present with clinical features mimicking those of a rheumatologic disease. Each of these aspects is considered separately in what follows.

Associations of rheumatologic diseases with cancer

An association between malignancy and autoimmune disease has been demonstrated for several rheumatologic disorders and has been hypothesized for others. The strongest association is that between adult-onset polymyositis or adult-onset dermatomyositis and malignancy. A full description of the details of this association is beyond the scope of this chapter; however, among patients with either polymyositis or dermatomyositis, the incidence of malignancy is increased, particularly the incidence of solid tumors. Polymyositis and dermatomyositis are associated with a significantly increased risk of developing lung cancer among men; in men, dermatomyositis is associated with a significantly increased risk of developing pancreatic carcinoma, and in women it is an associated risk for colon, breast, and ovarian carcinomas.¹ In addition, cases have been reported in which the inflammatory myopathy resolved after curative resection of the malignancy. Thus adults with polymyositis or dermatomyositis should be evaluated for evidence of an underlying malignancy; however, beyond age-appropriate screening tests, the extent of such an evaluation has not been clarified.

Another definite association is between rheumatoid arthritis (RA) or Sjögren syndrome (primary and secondary) and non-Hodgkin lymphoma.

Among patients with RA, the incidence of non-Hodgkin lymphoma (primarily B-cell lymphomas) is twofold to threefold that in the general population.² In patients with Sjögren syndrome, lymphocyte proliferation becomes more oligoclonal over time, and the incidence of non-Hodgkin lymphoma is fourfold to sixfold that of the general population. These associations are confounded by the possible increased risk of lymphoma conferred by some of the drugs used to treat these diseases, such as methotrexate, azathioprine, cyclosporine, cyclophosphamide, and tumor necrosis factor (TNF) antagonists. However, insufficient data exist to establish a causal relationship between treatments for RA and the development of lymphoma.²

Small observational studies suggest an association between systemic lupus erythematosus and malignancy, with an increased risk of developing breast, lung, and cervical carcinomas and lymphoid malignancies such as non-Hodgkin lymphoma that is unrelated to the use of cytotoxic agents. Although a retrospective study suggested an increased risk of lung carcinoma among patients with scleroderma and interstitial pulmonary fibrosis, this observation was not confirmed in a population-based cohort study.

Vasculitides, especially those associated with antineutrophil cytoplasmic antibodies (ANCA), may develop in association with myelodysplasia, hematologic and lymphoid malignancies, and solid tumors.³ Cutaneous leukocytoclastic vasculitis is associated more with the presence of hematologic malignancies than with solid tumors. Some patients with hairy cell leukemia, a rare B-cell lymphoproliferative disorder that usually presents as massive splenomegaly and pancytopenia, develop a cutaneous small-vessel vasculitis. Antiphospholipid antibodies, with or without vasculitis, may be present in patients with malignancy.

Other conditions seen by the rheumatologist may also be associated with malignancy. Both relapsing polychondritis and Sweet syndrome are associated with myeloproliferative disorders, especially myelodysplasia. Patients with multicentric reticulohistiocytosis may develop solid tumors. Patients with Paget disease of bone have an increased risk of developing osteogenic sarcomas, primarily in involved bones. Additionally, gouty arthritis can complicate chronic myeloproliferative disorders, and the aggressive treatment of leukemia and other malignancies can cause tumor lysis syndrome.

Musculoskeletal manifestations of cancer

Synovial sarcoma

Synovial sarcoma is an uncommon tumor that is misnamed because it arises from tissue adjacent to the joint and rarely, if ever, from the synovium.⁴ Although this tumor occurs most commonly between the third and fifth decades of life, it also may develop in children and adolescents. It generally presents as a mildly to moderately painful mass on a limb, more often on the leg, but it can be painless. These tumors adhere to adjacent structures, and symptoms are a consequence of local invasion. The average time from onset to diagnosis ranges from months to years, and these lesions are often misdiagnosed as benign growths before histologic analysis demonstrates them to be synovial sarcomas.

Radiographs may reveal a well-circumscribed soft tissue mass that frequently contains calcifications; however, in about half of synovial sarcomas, plain radiographs yield normal findings. Occasionally, periosteal reaction and even bone invasion is evident. Bone scans and computed tomography demonstrate the extent of the lesion and associated bony reaction. Angiograms reveal typical neovascularization and tumor blush. However, magnetic resonance imaging (MRI) with gadolinium-based contrast enhancement is the imaging procedure of choice because it shows the full extent of the lesion and the degree to which adjacent soft tissue structures, such as vessels and nerves, are involved. Additionally, MRI can help to localize the optimal

Fig. 170.1 (a) Radiograph of the digit of a patient with metastatic lung cancer shows destructive changes. (b) Inflammatory appearance of the same finger.

site for fine-needle aspiration biopsy to make a cytologic diagnosis. Surgical excision should include the tumor and its margin, if possible.

Grossly, the tumor is a circumscribed mass that adheres to the underlying tissue and to adjacent tissue structures. It is usually solid, but occasionally cystic changes may be noted. Because histologic evaluation of synovial sarcomas is difficult, expertise should be sought, and diagnoses are not infrequently changed on re-review of the tissue. Other tumors that may be confused with synovial sarcoma include epithelioid sarcomas, clear cell sarcomas, and fibrosarcoma.

The typical histologic pattern of synovial sarcomas is biphasic with two distinct cell types: fibrosarcoma-like spindle-shaped cells and epithelial cells. Spindle cells usually are the predominant cell type and have a characteristic swirling appearance with large nuclei and scant cytoplasm. These swirls appear to make clefts, at the border of which epithelial cells are often arranged. The more frequently mitotic figures are seen, the more de-differentiated the tumor, with a greater likelihood of vascular invasion and poorer prognosis. The epithelial cell component is occasionally sparse but can be visualized by silver stains that identify reticulin within the cytoplasm. The spindle cells have keratin, which can be identified by immunohistochemical analysis. Occasionally, only a single cell type (most often spindle cells) is seen, which creates difficulties in diagnosis.

Overall, the prognosis of synovial sarcomas is very poor. At the time of presentation, the tumor frequently has metastasized—often widely by hematogenous spread, most often to the lungs, and less frequently by local lymphatic spread. The 5-year overall survival is about 70%, with the prognosis being better for younger patients and for those with localized disease and tumors less than 5 cm in diameter.⁵

Treatment consists primarily of surgical resection, which usually achieves good results for small localized tumors with favorable histologic features. Radical resection, with or without amputation, is performed for larger, less well-differentiated tumors. Unfortunately, distant metastases are often discovered subsequently. Radiation therapy (40 to 75 Gy) is often administered after surgical resection, resulting in fewer relapses and better survival than among those treated with surgery alone. Combination chemotherapy with ifosfamide and doxorubicin (with or without vincristine) may be given before surgery and irradiation to improve survival and lengthen the disease-free interval.

Cartilaginous tumors

Cartilaginous tumors are discussed in Chapter 212.

Metastatic disease

Metastasis of lung or breast carcinoma and, infrequently, of kidney or prostate cancer to the proximal or distal end of long bones can present as joint

or periarticular swelling (Fig. 170.1). This typically occurs around the knee but may occur elsewhere, even in the small joints of the hands. Very infrequently, multiple metastatic lesions result from disseminated carcinoma. Cancer metastatic to the synovium has been reported infrequently.

Carcinomatous polyarthritis

Solid tumors, particularly of the breast and lung, are occasionally accompanied by an asymmetric inflammatory polyarthritis involving large and small joints. This nonerosive seronegative arthritis, which can present as RS3PE syndrome (remitting seronegative symmetrical synovitis with pitting edema) when associated with edema, may remit upon treatment of the underlying malignancy; otherwise, it can be treated with nonsteroidal antiinflammatory drugs (NSAIDs) or corticosteroids.⁶ Very infrequently, it can be an early clue to the presence of an occult malignancy.

Patients with pancreatitis, and occasionally those with pancreatic carcinoma,⁷ may develop a large joint arthritis, often involving the ankles, accompanied by intensely inflamed subcutaneous nodules that resemble erythema nodosum. These nodules, which are often several centimeters in diameter, may ulcerate and drain. Biopsy of the nodule reveals septal panniculitis similar to that seen in erythema nodosum but accompanied by fat necrosis that presumably results from release of pancreatic lipase. Synovial or bursal fluid obtained from these patients can appear milky because of the large numbers of fat droplets that result from necrosis of the fatty synovium.

Hypertrophic osteoarthropathy

Hypertrophic osteoarthropathy is discussed in Chapter 169.

Palmar fasciitis syndrome

Two publications in 1982^{8,9} reported the novel association of palmar fasciitis (Fig. 170.2) and ovarian carcinoma. These reports and subsequent case series described a syndrome that occurs in patients with a variety of neoplastic diseases: primarily ovarian but also breast, lung, pancreatic, and gastric carcinomas; Hodgkin disease; and chronic myelogenous leukemia.¹⁰ This syndrome may be difficult to distinguish from the complex regional pain syndrome (CRPS), but it generally spares the shoulders and, unlike CRPS, may be associated with synovitis. Biopsy of the palmar fascia reveals nodules or whorls of fibroblasts surrounded by dense connective tissue with fibrous septa. Some have suggested an autoimmune etiology, based on the presence of immunoglobulin deposits in biopsy specimens. However, because of its resemblance to CRPS, others consider it to be a variant of CRPS. Palmar fasciitis may improve with chemotherapy or surgery to treat the underlying malignancy, but many patients have widespread metastatic disease at the time of initial presentation.

Fig. 170.2 Palmar fasciitis. (a and b) Two views of the hands of a patient with palmar fasciitis secondary to a nonmalignant ovarian cyst. (c and d) Two views of the hands of the same patient after removal of the ovarian cyst demonstrating resolution of the findings.

Neoplastic conditions that mimic rheumatologic disease

Acute lymphoblastic leukemia

Childhood acute lymphoblastic leukemia (ALL) is the malignancy that is most difficult to distinguish from a rheumatologic disease and can be misdiagnosed as systemic-onset juvenile inflammatory arthritis.¹¹ Bone pain, often in a distribution that suggests juvenile RA, can be difficult to distinguish from joint pain. Fever, constitutional symptoms, rash, and anemia may occur both in childhood ALL and in systemic-onset juvenile inflammatory arthritis. Clinical features that prompt consideration of ALL include severe night pain, tenderness to palpation over long bones, lack of improvement with NSAID therapy, and the presence of leukopenia rather than leukocytosis. On plain radiographs, radiolucent lines near the epiphyses suggest the diagnosis of ALL. If there is any indication of ALL, examination of bone marrow is mandatory. In adults, both leukemia and lymphoma can mimic adult-onset Still disease; the presence of bone pain and lytic lesions should prompt consideration of a hematologic malignancy.

Angioimmunoblastic T-cell lymphoma

Angioimmunoblastic T-cell lymphoma (AITL), formerly called *angioimmunoblastic lymphadenopathy with dysproteinemia*, is a lymphoproliferative disorder that can be mistaken for an autoimmune disease because of its presentation with generalized lymphadenopathy, hepatosplenomegaly, fever, a maculopapular or urticarial rash, and constitutional symptoms. Occasionally, patients may develop a seronegative symmetric peripheral polyarthritis that usually does not respond to NSAIDs.¹² Polyclonal hypergammaglobulinemia, Coombs-positive hemolytic anemia, and other autoantibodies may be present. The diagnosis of AITL is based on its characteristic histologic appearance in which the lymph node architecture is partially to completely effaced by an infiltrate of lymphocytes, immunoblasts, and plasma cells that occupy predominantly the paracortical areas. Neoplastic T cells display clonal T-cell receptor gene rearrangements and express CXCL13, a

chemokine involved in migration of B cells into germinal centers, and CD10, a cell surface metalloproteinase. Cytogenetic studies reveal abnormalities of trisomy 3, trisomy 5, or gain of an X chromosome in approximately 70% of patients with AITL. Marked proliferation of small vessels, often with arborization, occurs within lymph nodes in AITL. The prognosis of AITL is poor compared with that of other forms of non-Hodgkin lymphoma, with a 5-year overall survival of 33% and a 5-year treatment failure-free survival of only 18%, even with combination chemotherapy.¹³

Multiple myeloma

Multiple myeloma may present as a variety of musculoskeletal problems, including carpal tunnel syndrome, destructive arthritis, or scleroderma-like skin changes caused by AL amyloidosis; bone pain; and pathologic fractures, primarily in elderly individuals. Other features of myeloma that suggest rheumatologic disease include elevation of the erythrocyte sedimentation rate (ESR), cryoglobulinemia with crystalline arthropathy, and polyneuropathy. Demonstration of lytic lesions on skeletal plain radiographs and of an increased number of plasma cells on bone marrow examination usually is sufficient to make the diagnosis of multiple myeloma.

Paraneoplastic syndromes

When a patient with an underlying malignancy has polyarthralgia and constitutional symptoms in the setting of circulating antinuclear antibodies or rheumatoid factor, the presentation occasionally can be confused with that of a systemic rheumatologic disease. Generalized aching, constitutional symptoms, and an elevated ESR, mimicking polymyalgia rheumatica, can occur in a variety of cancers; however, the subacute onset of these paraneoplastic symptoms helps to differentiate between these conditions. Infrequently, neoplasms that present as an asymmetric neuromyopathy may mimic dermatomyositis or polymyositis. However, these conditions usually can be distinguished by electromyography and muscle biopsy. Cavitory pulmonary nodules in patients with lung cancer can be mistaken for those of ANCA-associated granulomatous vasculitis.

Fig. 170.3 Multicentric reticulohistiocytosis. (a) Finger with glistening pearly-white nodules (string of pearls sign). (b) Radiographic appearance of digits showing destructive arthropathy.

OTHER SERIOUS SYSTEMIC SYNDROMES WITH RHEUMATOLOGIC FEATURES

Multicentric reticulohistiocytosis

Multicentric reticulohistiocytosis (Fig. 170.3) is a rare disorder characterized by the insidious onset of polyarthritis, which often evolves into a severe erosive deforming arthritis, and distinctive small, firm cutaneous papules and nodules on the skin. Skin lesions are pleomorphic, may be pruritic, and often occur around the joints. The most typical lesions are arranged in a string of pearls or coral bead pattern at the base of the nails. Joint involvement is symmetric and similar in distribution to that in RA except that distal interphalangeal joints are frequently involved. If left untreated, this arthritis is very destructive. Multicentric reticulohistiocytosis occurs predominantly, but not exclusively, in adults and three times as often in women as in men.

There are no characteristic laboratory findings, although most patients have a mild anemia, 30% to 60% have hyperlipidemia, and up to 50% display reactivity to purified protein derivative. The diagnosis is confirmed by biopsy of skin lesions or synovium, which reveals lipid-laden histiocytes and multinucleated giant cells that express the osteoclast markers tartrate-resistant acid phosphatase and cathepsin K. Interestingly, some patients also have a coexisting autoimmune disease or malignancy. The mechanism of disease is unknown, but increased synovial macrophage and endothelial cell staining for TNF- α , interleukin-1 β (IL-1 β), IL-6, and IL-12 has been described.¹⁴

Although no treatment is consistently effective for multicentric reticulohistiocytosis, methotrexate, cyclophosphamide, alendronate, and zoledronate have been used with success. TNF antagonist therapy has resulted in improvement in both skin and joint involvement.¹⁵

Castleman disease

Castleman disease, also known as *giant lymph node hyperplasia*, was first described in 1956 in 13 patients with mediastinal lymphadenopathy characterized by germinal-center formation and marked capillary proliferation. Pathologically it can be divided into two groups: a hyaline vascular type (90%) and a plasma cell type (10%). Patients frequently are asymptomatic, but some patients with the plasma cell variant may have diffuse extrathoracic lymphadenopathy with a variety of systemic symptoms. This multicentric form of Castleman disease is often accompanied by anemia, an elevated ESR, and polyclonal hypergammaglobulinemia. When autoimmune serologic features are present, it may mimic a systemic autoimmune disease such as systemic lupus erythematosus or Sjögren syndrome. About half of patients with multicentric Castleman disease die, most commonly of sepsis or malignant transformation of the lymph node hyperplasia into lymphoma; median survival is 26 months. When multicentric Castleman disease occurs

in the setting of human immunodeficiency virus (HIV) infection, usually accompanied by human herpesvirus 8 (HHV-8) coinfection, median survival is reduced to 14 months.

B cells in the germinal centers of affected lymph nodes in patients with the plasma cell variant of multicentric Castleman disease produce increased amounts of IL-6, and these patients have elevated serum IL-6 levels. Treatment of patients with multicentric Castleman disease with rituximab, which depletes B cells, improves clinical outcome and overall survival both among those coinfecting with HIV and HHV-8 and among those not infected with either virus. Administration of tocilizumab, a monoclonal antibody to the IL-6 receptor, effectively reverses the signs and symptoms of multicentric Castleman disease.¹⁶

POEMS syndrome

Patients with the rare POEMS syndrome present with a slowly progressive demyelinating polyneuropathy, organomegaly, a variety of endocrinologic features including diabetes and hypogonadism, monoclonal gammopathy, skin changes, and sclerotic bone lesions.¹⁷ Some patients with clinical features of the POEMS syndrome may have histologic features of Castleman disease. Proinflammatory cytokines such as IL-1 β , TNF- α , and IL-6 and growth factors such as vascular endothelial growth factor mediate this syndrome, which may mimic systemic rheumatologic disease. Although controlled trials of therapy have not been conducted, successful treatments have included irradiation of osteosclerotic lesions, corticosteroids, alkylating agents such as melphalan, thalidomide, lenalidomide, bortezomib, and high-dose chemotherapy with autologous peripheral blood stem cell transplantation.¹⁸

Whipple disease

In 1907, Dr. George Hoyt Whipple, Nobel laureate in medicine and physiology, described a 36-year-old physician who had been working as a medical missionary in Constantinople and developed cough, shortness of breath, and periodic arthritis. The patient experienced episodes of joint inflammation that lasted for 6 to 8 hours. Many different joints were affected, and he gradually lost weight and developed chronic diarrhea with fat malabsorption. Later, he developed dark skin and abdominal swelling, with probable ascites. Joint radiographs revealed only soft tissue swelling. In spite of being force-fed a diet that included four raw eggs a day, the patient lost weight and died. On autopsy a peculiar "intestinal lipodystrophy" was observed. These findings characterize a rare disease that was named *Whipple disease*.

In 1961, the cause of Whipple disease was identified by electron and light microscopy as a periodic acid-Schiff (PAS)-staining organism; this fastidious bacterium was subsequently named *Tropheryma whippeli* and grown in culture. *T. whippeli* has been detected in synovial fluid and tissue

of affected individuals by polymerase chain reaction (PCR) testing,¹⁹ even in those in which characteristic PAS staining of tissue is absent.

Whipple disease is uncommon, with an annual incidence of less than 1 per 1,000,000 population, and occurs primarily in middle-aged white males.²⁰ Individuals who work on farms, are receiving treatment with biologic agents, or have immunodeficiency syndromes or chronic kidney disease may be more susceptible. A migratory arthritis affecting predominantly large joints occurs in about 75% of patients with Whipple disease and often is the initial clinical manifestation. Some patients may develop spondyloarthritis and are found to be positive for HLA-B27. Other clinical features include uveitis, cardiac involvement, and a pathognomonic central nervous system manifestation known as *oculofacioskeletal* (or *oculomastatory*) *myorhythmia*. Late manifestations include dementia and cerebellar dysfunction. Most patients with Whipple disease demonstrate evidence of an acute-phase response, with anemia, thrombocytosis, and elevation of ESR and C-reactive protein level.

The diagnosis is confirmed by endoscopic biopsy of thickened duodenal mucosal folds demonstrating PAS-positive inclusions within macrophages of the lamina propria.²⁰ *T. whipplei* can be detected by PCR testing of body fluids, including saliva, or tissue if the diagnosis is equivocal. Celiac disease and tuberculosis, which enter into the differential diagnosis of Whipple disease, should be excluded.

Most patients do well with antibiotic therapy, although the time to response is variable and the optimal antibiotic regimen and treatment duration are unknown. Recommended treatment is oral trimethoprim/sulfamethoxazole or sulfamethoxazole given for 12 months, often preceded by 2 weeks of parenteral meropenem or ceftriaxone.²¹ Alternatively, hydroxychloroquine, which reduces the acidity of the intracellular vacuole in which the bacterium is located, can be added to doxycycline to increase the bactericidal activity of the antibiotic against *T. whipplei*.

SYNDROMES WITH PREDOMINANTLY MUSCULOSKELETAL INVOLVEMENT

Bypass arthritis

Patients who underwent jejunoileal (but not gastric) bypass surgery for weight reduction frequently experienced an intermittent polyarthritis with constitutional symptoms.²² This procedure now is rarely performed because of these complications. Occasionally, papular skin lesions with leukocytoclastic vasculitis and immune complexes evident on skin biopsy would accompany attacks of joint inflammation. These were thought to result from blood-borne dissemination of bacterial debris or immune complexes from the blind loop created by the surgery. The arthritis and skin lesions both were exquisitely painful, similar to those of the gonococcal arthritis/dermatitis syndrome. Patients also could develop other symptoms of immune complex disease, such as polyserositis and mild glomerulonephritis. Synovial fluid typically was inflammatory, but no specific abnormalities were evident on laboratory testing. Antibiotic treatment of blind loop syndrome often led to improvement of symptoms. Notwithstanding, some patients needed to have the jejunoileal bypass reversed because of persistent articular and cutaneous inflammation.

Foreign body synovitis

Foreign body synovitis is an unusual form of arthropathy that has been described primarily as monoarticular arthritis occurring after a penetrating injury from a foreign object.²³ These foreign objects can be categorized as either organic material (usually plant thorns, sea urchin spines, and seashell fragments) or inorganic material (natural or manufactured) (Box 170.1). The typical patient who develops synovitis from an organic foreign body is a young man engaged in an endeavor such as an agricultural or marine activity that puts him at risk of penetrating injury. Involved joints include those that are most susceptible to penetrating injuries, predominantly the hands and knees. Fragments of inorganic material resulting from wear of prosthetic joints (predominantly polyethylene, metallic particles, and acrylic cement) may cause synovitis around a prosthetic joint.²⁴

Foreign body synovitis generally presents as acute or subacute monoarticular arthritis, but inflammation may be episodic. Synovial fluid is inflammatory, typically revealing between 5000 and 50,000 white blood cells/mm³ and a predominance of polymorphonuclear neutrophils. Cultures are usually sterile, although, on rare occasions, the foreign material may introduce infection and cause a coexisting septic arthritis. Radiographs are sometimes helpful in diagnosing foreign body synovitis. Radiopaque foreign material can be identified by plain radiography; however, the vast majority of

BOX 170.1 REPORTED ASSOCIATIONS OF FOREIGN BODY SYNOVITIS

	Teflon
	Metal

vegetable material is radiolucent. Standard radiographs usually show only soft tissue swelling, but erosive changes have been observed.

The inflammatory reaction to a sterile foreign body typically produces a nonspecific granulomatous synovitis that can be demonstrated on synovial biopsy, performed by either a closed or open technique. This histologic appearance can be mistaken for that of a variety of other granulomatous diseases, such as sarcoidosis. Thus, when a foreign body is suspected as the cause of synovitis, the pathologic specimen should be examined using polarizing microscopy, which often reveals a birefringent structure suggestive of plant material. Appropriate treatment requires excision of the foreign body and involved synovium.

Silicone synovitis

Silicone-containing joint prostheses may fracture and generate wear particles, which are ingested by macrophages and generate an inflammatory response. This reaction can lead to destructive synovitis, particularly in the wrist; consequently, most surgeons have abandoned silicone-containing carpal implants. However, silicone-containing implants are still used to replace the metacarpophalangeal, proximal interphalangeal, and metatarsophalangeal joints, in which silicone-induced synovitis occurs much less frequently and, when present, is more limited in its extent. Treatment of this inflammatory condition is directed toward control of symptoms, which may require removal of the prosthesis and synovectomy.²⁵

Intermittent hydrarthrosis

Intermittent hydrarthrosis is an uncommon syndrome affecting women that is characterized by symmetric joint effusions, predominantly involving the knees, and that does not result in joint destruction. These effusions occur periodically, often monthly at or around the menses. Patients with intermittent hydrarthrosis experience mild to moderate joint pain and stiffness when the disease is active. Aspirated synovial fluid is either bland or reflects mild inflammation. Low-dose colchicine has prevented recurrent attacks of intermittent hydrarthrosis.²⁶ Heterozygous disease-associated mutations in the *MEFV* gene, which encodes the pyrin/marenostrin protein, have been identified in patients with intermittent hydrarthrosis but without other features of familial Mediterranean fever.²⁷ This suggests that intermittent hydrarthrosis might be a mild, localized inflammatory disease that is part of the spectrum of periodic fever syndromes.

Palindromic rheumatism

A palindrome is a word or phrase that is arranged symmetrically about an axis. The most famous palindrome is the sentence attributed to Napoleon, "Able was I ere I saw Elba." Palindromic rheumatism is an intermittent inflammatory condition that affects one or, at most, a few joints in an unpredictable pattern that lasts for hours to several days. Affected joints are swollen, warm, and tender; may exhibit overlying erythema; and yield inflammatory joint fluid when aspirated.²⁸ Palindromic rheumatism may affect the same or different joints in repeated attacks. Levels of acute-phase reactants may be elevated during attacks but not in the intercurrent period.

Between attacks, affected joints are normal and joint damage usually does not develop.

Attacks of palindromic rheumatism may persist or resolve spontaneously, but approximately one third of patients (especially those with circulating rheumatoid factor or anti-citrullinated protein antibodies) develop conventional RA. Patients may be treated with NSAIDs or glucocorticoids during attacks, but these medications do not shorten the duration of joint inflammation. Hydroxychloroquine and other disease-modifying antirheumatic drugs have been used to prevent attacks but have not been evaluated systematically.

Crystal arthropathies and other intermittent disorders, such as familial Mediterranean fever, should be considered in the differential diagnosis. As in several patients with intermittent hydrarthrosis, disease-associated mutations in the *MEFV* gene were identified in 8 (12.3%) of 65 patients with palindromic rheumatism.²⁹

Fibroblastic rheumatism

Fibroblastic rheumatism is a rare syndrome characterized by multiple firm skin nodules and a symmetric polyarthritis with a distribution similar to that of RA, but also involving the distal interphalangeal joints, that often results in sclerodactyly and joint contractures.³⁰ The arthritis has been described as inflammatory and may be erosive, even mimicking that of multicentric reticulohistiocytosis. Biopsy specimens from skin nodules

demonstrate increased dermal fibroblasts and myofibroblasts and thickened collagen fibers, with loss of elastic fibers and no mucin deposition. Some have described lymphocytic infiltrates in the early lesions. Occasional synovial biopsy specimens have shown similar findings. Fibroblastic rheumatism may remit spontaneously, but subsequent exacerbations often occur. Various antiinflammatory and antirheumatic drugs have been used, including corticosteroids, methotrexate, and TNF antagonists, but there is no known effective therapy. The differential diagnosis includes scleroderma, palmar fasciitis with contractures that occurs in the setting of various carcinomas, and pachydermodactyly, which is benign localized fibrosis around the proximal interphalangeal finger joints.

Pigmented villonodular synovitis

Pigmented villonodular synovitis (PVNS) (Fig. 170.4) is a benign proliferation of synovial tissue that usually presents as an indolent, progressive monoarticular arthritis or tenosynovitis. Clinically it is divided into three forms: (1) an isolated tenosynovitis that often involves the hand, also known as *tenosynovial giant cell tumor*; (2) a diffuse form commonly found in the knee; and (3) a localized form that moves freely in the joint.

Pigmented villonodular tenosynovitis typically presents as an enlarging mass adherent to a tendon; it usually occurs in adults and is more common in women than in men. Its appearance is similar to that of a ganglion, and it never becomes malignant. Tendon and adjacent bone can be damaged if

Fig. 170.4 Pigmented villonodular synovitis. (a) Magnetic resonance image of the knee. Short wide arrows indicate joint effusion in the suprapatellar pouch, and there is a lobulated mass with a typical dark image on T2-weighted scans in the popliteal fossa just below the long arrow. (b) Photomicrograph showing clusters of cells with large pale nuclei and foamy cytoplasm, giant cells, and hemosiderin in the right lower corner. (c) Gross appearance of synovium with pigmented nodules.

Fig. 170.5 SAPHO syndrome. (a) Palmoplantar pustulosis. (b) Hidradenitis suppurativa. (From Carneiro S, Sampaio-Barros PD. SAPHO syndrome. *Rheum Dis Clin North Am* 2013;39:401-18.)

the disease remains untreated. Treatment consists of complete surgical removal of the pathologic synovium. Recurrences can occur, especially if excision has been incomplete.

The diffuse form of PVNS presents as slowly progressive, painful swelling of a single joint.³¹ The knee is the joint most commonly affected, with the hip and ankle being the next most often involved. Rarely, it can occur in other appendicular joints or in the spine. This form of PVNS damages joints with a tight capsule, such as the hip or zygapophyseal (facet) joints of the spine. It often generates the characteristic radiographic appearance of scalloped erosions, usually with a sclerotic margin at the site of synovial insertion or reflection, which is thought to result from pressure on or direct invasion of bone by the synovial mass. Associated joint effusions can be brown or hemorrhagic.

Localized PVNS is the least frequently occurring form. It projects as a pedunculated nodule into the synovial cavity, often of the knee, where it can cause signs and symptoms of a loose body. Patients with the localized form of PVNS typically experience mild pain and locking of the affected joint.

PVNS is not visible on plain radiographs.³¹ However, on MRI it is seen as a dark soft tissue mass with intermediate to low signal intensity on T1-weighted images and low signal intensity on T2-weighted images because of hemosiderin deposition.

The cause of PVNS is unknown, but the histologic appearance of all three types is identical and all are thought to share a common pathogenesis. Microscopically, there is a proliferation of sheets of pale-staining synovial cells, foam cells that contain lipid and hemosiderin, and multinucleated giant cells, which results in a hypertrophic red-brown and occasionally yellow-hued tissue.³² Hemophilia, hemosiderosis from recurrent hemarthroses, and hemochromatosis can also produce iron-pigmented tissue. Thus not all brown-stained proliferative synovitis is PVNS. PVNS might be thought of as analogous to pannus in RA. Some investigators propose that hemorrhage into the joint plays a role in the pathogenesis of the lesion. However, attempts to reproduce the lesion by injecting blood into the joint cavities of animals have resulted in an inflammatory synovitis that most closely resembles the arthropathy that accompanies hemophilia rather than PVNS.

Several patients with PVNS have responded to either systemic or intra-articular administration of a TNF antagonist or oral administration of imatinib mesylate.³³ However, PVNS is usually treated by thorough surgical excision. This usually cures pigmented villonodular tenosynovitis and the localized pedunculated form of PVNS, but surgery is substantially less effective and less satisfactory in treating the diffuse form. Arthroscopic resection alone is inadequate therapy for diffuse PVNS. It is quite difficult to achieve an adequate resection of diffuse PVNS in the knee or hip; thus recurrences are frequent. In diffuse disease in which bony destruction has been caused by the lesion, synovectomy combined with total joint arthroplasty remains the most successful approach.³⁴

It is particularly difficult to perform a curative resection of PVNS in the vertebral column. Radiotherapy long has been attempted to treat nonresectable and recurrent disease. Both yttrium-90 silicate and dysprosium-65 ferric hydroxide macroaggregate have been used with some success, often in combination with extensive surgical débridement. External irradiation is not commonly used to treat PVNS.

SAPHO syndrome

SAPHO is an acronym designating a syndrome that contains some or all of the following clinical features: synovitis, acne, pustulosis, hyperostosis, and osteitis. This uncommon disorder usually affects young adults but has been observed in patients of all ages, including children and the elderly, and has

been known by a variety of names, including *recurrent multifocal osteomyelitis* and *acne-induced arthritis*. The term SAPHO was coined in 1987 and refers to a heterogeneous disorder, the hallmarks of which include osteosclerotic bone lesions with sterile osteomyelitis and a variety of skin lesions. Approximately half of patients with SAPHO syndrome have palmoplantar pustulosis; the others may have a variety of skin manifestations that include psoriasis, hidradenitis suppurativa, severe acne, and, infrequently, Sweet syndrome (Fig. 170.5).

The bone lesion typical of SAPHO syndrome is osteosclerotic hyperostosis, which often involves the acromioclavicular and sternoclavicular joints. Other sites where these bone lesions typically develop include the anterior chest wall, sternum, clavicle, symphysis pubis, thoracic and cervical spine, and mandible. These sclerotic bone lesions demonstrate increased radionuclide uptake on technetium-99m bone scanning; cultures of bone biopsy specimens usually are sterile but occasionally grow *Propionibacterium acnes*. A sterile, but erosive, inflammatory synovitis can develop in joints adjacent to bone lesions. SAPHO syndrome can be considered to be spondyloarthritis: approximately 13% of patients have the HLA-B27 gene, and about one third of patients have sacroiliitis or spondylitis. Around 10% of patients with SAPHO syndrome also have inflammatory bowel disease, with a predominance of Crohn disease.³⁵

Patients are likely to remain symptomatic; however, SAPHO syndrome does not appear to be overwhelmingly disabling. This disorder is typically characterized by sporadic outbreaks or attacks during which new osteosclerotic bone lesions develop. Skin lesions tend to be more persistent and less responsive to therapy than osteoarticular manifestations. It is not known if aggressive treatment of the skin disease ameliorates the bone disorder.³⁵

NSAIDs and intra-articular corticosteroid injections provide effective treatment for the majority of patients with SAPHO syndrome.³⁵ Most of those in whom NSAID therapy fails show a response to systemic corticosteroids. Nevertheless, some patients require methotrexate to treat progressive disease. Several patients have been given prolonged courses of doxycycline empirically to treat a presumed infectious agent, even when biopsy shows no evidence of infection; this has been associated with improvement in a few cases. TNF antagonist treatment has improved both skin and osteoarticular disease.³⁶ Several patients with SAPHO syndrome also have been treated successfully with bisphosphonates, including pamidronate, zoledronic acid, and alendronate.

Synovial osteochondromatosis

Synovial osteochondromatosis (Fig. 170.6) is an uncommon condition that results from metaplasia of synovial tissue into cartilage, which can subsequently calcify or ossify.³⁷ However, the factors that precipitate the development of synovial osteochondromas are incompletely understood. Patients have joint pain, swelling, and tenderness, usually in a monoarticular distribution, and may experience locking of the affected joint. Over half of cases occur in the knee; the hip and elbow are also commonly affected, but involvement of many other joints or bursae also has been described. Although the disorder occurs in children, most patients with synovial osteochondromatosis are older, with an average age between 30 and 50 years. Men are affected slightly more often than women.

The pathogenesis of synovial osteochondromatosis is unknown, but the synovium is strikingly hypertrophied with numerous villi. Cartilaginous nodules are present both within the synovium and free within the synovial cavity. Malignant transformation has been reported very infrequently.

Plain radiographs show the characteristic appearance of “popcorn” within the joint cavity if the lesions are calcified. Uncalcified lesions can be visualized by MRI. The differential diagnosis includes loose bodies from trauma and tumoral calcinosis. No detailed analyses of synovial fluid have

Fig. 170.6 Synovial osteochondromatosis. (a) Radiograph of knee with typical “popcorn”-shaped calcification. (b) Synovial biopsy specimen showing osteochondrometaplasia on the left (hematoxylin-eosin).

been reported, but calcium pyrophosphate dihydrate (CPPD) crystals have been described in association with synovial osteochondromatosis.

NSAIDs are typically administered for pain control. Operative management involves removal of loose bodies and synovectomy, either by open arthrotomy or by arthroscopy.

Diabetic muscle infarction

Diabetic muscle infarction is an infrequent complication of long-standing diabetes mellitus that also has been called *aseptic myonecrosis* and *ischemic myonecrosis*. It presents as the acute onset of muscle pain and swelling, most commonly in the thigh, and may be accompanied by mild constitutional symptoms. Patients with type 1 and type 2 diabetes mellitus are affected, usually after more than 10 years of disease; most also have diabetic microvascular complications, such as nephropathy, neuropathy, and retinopathy.³⁸ Diabetic muscle infarction probably occurs as the result of an initial small thromboembolic event that causes ischemia because of impaired collateral circulation in the setting of diabetic microvascular disease, with resulting edema and compartment syndrome that causes further muscle ischemia; however, the hypoxic muscle damage results in a significant inflammatory response, hyperemia, and reperfusion with generation of reactive oxygen species that cause additional edema and compartment syndrome with further muscle damage.³⁹

Laboratory testing may reveal elevation of creatine phosphokinase levels or ESR. Electromyography demonstrates nonspecific abnormalities. MRI is the imaging technique of choice to evaluate diabetic muscle infarction and demonstrates hyperintense signal of infarcted muscle, muscle enlargement, and subcutaneous and subfascial edema on T2-weighted images.⁴⁰ Biopsy usually is not necessary and, because of potential infectious and wound healing complications, should be reserved for cases in which the diagnosis is uncertain or pyomyositis is suspected.

Patients should rest and take analgesic medications. Treatment with antiplatelet agents and antiinflammatory medications may hasten recovery.⁴⁰ Conversely, surgical resection may delay recovery and increase the risk of recurrence and mortality from complications of diabetic macrovascular disease compared with medical or conservative therapy.

Retroperitoneal fibrosis

Idiopathic retroperitoneal fibrosis typically presents as a periaortic mass with associated back or abdominal pain, often with obstructive nephropathy due to encasement of the ureters. This rare disease, with an annual incidence of 1.3 per 100,000 population, occurs more commonly in older males.⁴¹ In most cases, the fibrosis occurs between the renal artery and the bifurcation of the aortic aorta, but it may extend superiorly or inferiorly. Extraperitoneal fibrosis, such as Riedel thyroiditis, mediastinal fibrosis, sclerosing cholangitis with autoimmune pancreatitis, and orbital pseudotumor, occurs in some patients with retroperitoneal fibrosis. The finding of increased numbers of immunoglobulin G4 (IgG4)-positive plasma cells in biopsy samples from patients with idiopathic retroperitoneal fibrosis as well as from those with extraperitoneal fibrosing syndromes has prompted grouping of these conditions as “IgG4-related disease.”⁴²

Fig. 170.7 Retroperitoneal fibrosis. Biopsy specimen from the affected area demonstrates extensive fibrosis and lymphocytic inflammatory infiltrate.

Retroperitoneal fibrosis has been described in association with a number of rheumatologic diseases, including ankylosing spondylitis, systemic lupus erythematosus, polyarteritis nodosa, and ANCA-associated granulomatous vasculitis. Its occurrence in the setting of treatment with certain medications, such as methysergide and other ergot derivatives, has suggested a causative role for these drugs. Atherosclerotic plaque extruded from the aorta, in which the immunogenic material appears to be ceroid and oxidized low-density lipoproteins, also has been proposed as a potential cause. Most patients with retroperitoneal fibrosis have increased levels of acute-phase reactants, and many have circulating antinuclear antibodies.⁴¹

Biopsy of retroperitoneal fibrotic lesions is appropriate to assess the degree of inflammation and to exclude the diagnosis of sarcoma or lymphoma (Fig. 170.7). Computed tomographic scanning is the imaging procedure of choice to diagnose the disease (Fig. 170.8a) and follow the response of retroperitoneal fibrosis to treatment (Fig. 170.8b).

Initial treatment usually involves stenting or surgery to relieve ureteral obstruction. Medical therapy consists of high-dose corticosteroids, often with the addition of steroid-sparing immunosuppressive drugs. Both azathioprine and cyclophosphamide have been used with success.⁴³ Treatment with either the estrogen receptor antagonist tamoxifen or mycophenolate mofetil,⁴⁴ in combination with corticosteroids, has resulted in regression of retroperitoneal fibrosis in some patients.

MUSCULOSKELETAL SYNDROMES ASSOCIATED WITH CHRONIC KIDNEY DISEASE

Musculoskeletal complications are reported to occur in more than one half of patients receiving long-term hemodialysis, but the studies investigating the prevalence of these conditions are limited by the relatively small number of patients examined.⁴⁵ As of December 31, 2011, 430,273 people in the United States were treated with dialysis for stage 5 chronic kidney disease. (According to the 2013 U.S. Renal Data System Annual Data Report and the U.S. Census Bureau, the U.S. population at that time was 312,780,968.)

Fig. 170.8 Retroperitoneal fibrosis. (a) At the time of presentation for back pain, the patient had extensive fibrosis in the retroperitoneum, as seen in this computed tomographic image. The fibrosis encases the paravertebral muscles. (b) After several months of corticosteroid therapy (1 mg/kg/day of prednisone), the patient's fibrosis had improved significantly.

If only half of those patients who receive long-term hemodialysis in the United States have musculoskeletal symptoms, then a conservative estimate of the prevalence of musculoskeletal conditions among patients with stage 5 chronic kidney disease is comparable to the prevalence of systemic lupus erythematosus in the general population.

Arthritis and periartthritis

Arthritis, tendinitis, and enthesitis among patients receiving long-term dialysis frequently prompt the request for rheumatologic consultation. Although common in patients with chronic kidney disease before the initiation of dialysis treatment, acute attacks of gouty arthritis are uncommon in hyperuricemic individuals with uremia. The inflammatory response to monosodium urate crystals is diminished in patients receiving long-term hemodialysis, with decreased monocyte release of IL-1 β , IL-6, and TNF- α compared with individuals with normal renal function. Moreover, dialysis modalities remove urate efficiently and thus facilitate the dissolution of urate deposits in patients with gout.

Joint and periarticular inflammation caused by apatite (basic calcium phosphate) crystals occur more commonly than acute gouty arthritis in these patients, especially when the serum calcium-phosphorus product exceeds 75 mg²/dL². Other calcium-containing crystals may deposit in and around articular tissue; CPPD crystals may cause either an acute, robust inflammatory arthritis, similar to that of acute gout, or a chronic, smoldering synovitis. Calcium-containing crystals most commonly deposit around the shoulder, but deposits also may occur around the small joints of the hand, the hip, the wrist, the ankle, and the elbow. These deposits, which appear on radiographs of the shoulder as "multiloculated," nodular, periarticular calcifications, may enlarge to become palpable and visible masses (called *tumoral calcinosis*). Limited calcification in tendons, ligaments, and the joint capsule may be associated with acute attacks of painful periarticular inflammation (Fig. 170.9). Partial or complete tendon ruptures may also occur, often without antecedent symptoms, especially in the setting of uncontrolled secondary hyperparathyroidism. However, with better control of hyperphosphatemia and hyperparathyroidism in recent years, calcific periartthritis is no longer as prevalent as it was earlier.

Calcium oxalate crystals can cause acute and chronic synovitis. Although small joints of the distal extremities are more commonly affected, large joints may also become inflamed. Chondrocalcinosis may be evident on radiographs of involved joints. Calcium oxalate crystals may also deposit in vascular smooth muscle, resulting in acrocyanosis and livedo reticularis. Because ascorbic acid (vitamin C) is metabolized to oxalate, caution should be observed in prescribing vitamin C supplementation for these patients.⁴⁶

Fig. 170.9 Periarticular calcium hydroxyapatite deposition in the hands of a patient receiving long-term hemodialysis.

Monosodium urate, CPPD, and calcium oxalate crystals can be identified without difficulty by compensated polarizing light microscopy; however, the identification of apatite and basic calcium phosphate crystals is more difficult because of their small size. Alizarin red S (0.1% weight per volume in water, titrated to pH 6.4 with 0.1 N formic acid, prepared freshly every few months) will stain apatite and other calcium-containing crystals in synovial fluid. A small drop of the stain should be placed on the edge of the wet-mount coverslip should an initial examination of the preparation fail to reveal birefringent crystals. The dye will diffuse across the slide within several seconds and stain calcium-containing crystals bright red, whereas the background will remain reasonably clear.

Bacterial infections of bursae and joints occur in individuals undergoing hemodialysis in whom percutaneous vascular access is established several times each week. The most common pathogenic organism is *Staphylococcus aureus*. Diagnosis (by joint aspiration with examination and culture of synovial fluid) and treatment are as for nonuremic patients.

Initial clinical laboratory evaluation of the patient with chronic kidney disease and articular or periarticular inflammation should include assessment of serum calcium, phosphate, albumin, uric acid, and intact parathyroid hormone levels. Phosphatonins, such as fibroblast growth factor 23 and

matrix extracellular phosphoglycoprotein, are phosphaturic factors that mediate forms of hypophosphatemic rickets and oncogenic osteomalacia. Fibroblast growth factor 23, levels of which are elevated in patients with chronic kidney disease, is an important inhibitor of renal 1α -hydroxylation of 25-hydroxyvitamin D and thus of phosphate absorption from the gastrointestinal tract. Although measurement of phosphatonins remains investigational, understanding how to modulate these factors should allow for more effective control of calcium and phosphate levels in patients with stage 5 chronic kidney disease.

β_2 -Microglobulin amyloidosis

β_2 -Microglobulin amyloidosis is a systemic infiltrative disease that affects patients with severe chronic kidney disease, predominantly those who have received long-term hemodialysis. β_2 -Microglobulin is an 11.8-kDa protein that is required for expression of HLA class I molecules, to which it is non-covalently bound, on the surface of nucleated cells. Usually cleared by renal filtration, β_2 -microglobulin was inadequately cleared by traditional dialysis modalities, especially hemodialysis using low-flux bioincompatible cellulose-derived membranes that are poorly permeable to “middle molecules” of 0.3 to 5 kDa and to low-molecular-mass proteins. Synthesis and secretion of proinflammatory cytokines by peripheral blood leukocytes coming in contact with bioincompatible dialysis membranes and with bacteria in the dialysate solution also increased β_2 -microglobulin synthesis. Since the early 1990s, coincident with the widespread use of biocompatible synthetic dialysis membranes such as polysulfone and polyacrylonitrile and of purified dialysate solutions, the occurrence of β_2 -microglobulin amyloidosis has decreased markedly.

Although β_2 -microglobulin amyloid deposits have been detected in joint tissue in patients with long-standing stage 5 chronic kidney disease before the initiation of dialysis treatment, this disease usually does not become clinically evident until a patient has undergone regular dialysis for several years. The prevalence of β_2 -microglobulin amyloidosis increases with longer

duration of survival on long-term dialysis treatment and with older patient age. However, in developed countries, this disease now is seen only in patients who have received hemodialysis or peritoneal dialysis for longer than 20 years.

The characteristic triad of shoulder periartthritis, carpal tunnel syndrome, and flexor tenosynovitis is highly suggestive of β_2 -microglobulin amyloidosis in a patient receiving long-term dialysis treatment (Fig. 170.10).⁴⁵ Other skeletal manifestations include rapidly enlarging cystic erosions of bone by β_2 -microglobulin amyloid-containing synovium, which most often occur in the carpal bones and in the femoral neck, and destructive spondyloarthritis with a radiographic appearance resembling that of diskitis, which is observed predominantly in the lower cervical spine (Fig. 170.11). In some patients receiving long-term dialysis treatment, β_2 -microglobulin amyloid is deposited in the extradural space, sometimes causing spinal cord or nerve root compression, and around the odontoid process of C2, forming a cervicocapital pseudotumor. However, this polyarticular destructive change now is rarely seen. Systemic deposition of β_2 -microglobulin amyloid has been described in the skin, the heart, and the gastrointestinal tract, where it can cause malabsorption and colonic ulceration in patients who have undergone hemodialysis for many years.

Serum β_2 -microglobulin levels decrease rapidly and joint pain and stiffness improve after renal transplantation. Bone cysts no longer enlarge in patients with functioning renal allografts; however, the destructive spondyloarthritis may progress. Short of renal transplantation, hemodialysis using a biocompatible synthetic membrane and purified dialysate should be performed to prevent β_2 -microglobulin accumulation. Because no medical treatment has altered the course of this disease, individual manifestations should be managed separately. The greater risk of infection associated with intraarticular corticosteroid injections in dialysis patients should be weighed carefully against the brief duration of symptomatic improvement that this therapy may provide. The risk of NSAID toxicity, especially gastrointestinal effects, is greater among patients with stage 5 chronic kidney disease, and their use should be limited. Analgesics and low-dose oral corticosteroids are

Fig. 170.10 β_2 -Microglobulin amyloidosis. (a) Shoulder periartthritis with typical “shoulder pad” sign. (b) Flexor tenosynovitis with irreducible flexion contractures of the fingers and a subcutaneous soft tissue mass in the palm. (From Kay J. *Beta 2-microglobulin amyloidosis*. *Rheumatol Rev* 1993;2:211-8.)

Fig. 170.11 β_2 -Microglobulin amyloidosis. (a) Radiograph of wrist showing multiple subchondral cysts in the carpal bones, at the bases of the metacarpal bones, and in the distal radius. (b) Lateral cervical spine radiograph showing changes characteristic of destructive spondyloarthritis. The intervertebral disk spaces between the third and fourth cervical vertebrae and between the fifth and sixth cervical vertebrae are narrowed and the vertebral endplates are eroded without appreciable formation of osteophyte. (From Kay J. *Beta 2-microglobulin amyloidosis*. *Amyloid* 1997;4:187-211.)

better options to treat patients with β_2 -microglobulin amyloidosis who experience persistent pain. Rehabilitation modalities should be used to treat the frequent symptoms of impingement syndrome that develop because of amyloid infiltration of the supraspinatus tendon and to prevent finger flexion contractures caused by chronic palmar flexor tenosynovitis. Neutral resting wrist splints may be worn to improve symptoms of carpal tunnel syndrome. When necessary, carpal tunnel release and hand flexor tenosynovectomy surgery may be performed. At the time of surgery, tissue should be obtained for confirmation of the diagnosis by Congo red staining and by immunohistochemical techniques using antibodies to β_2 -microglobulin.

Nephrogenic systemic fibrosis

Nephrogenic systemic fibrosis (NSF), originally called *nephrogenic fibrosing dermopathy*, was first observed in 1997 among renal transplant recipients and first described in 2000 as a condition that resembled scleromyxedema in 14 patients with stage 5 chronic kidney disease who were receiving hemodialysis.⁴⁷ However, unlike scleromyxedema, NSF spares the face and is not associated with circulating paraproteins. When significant visceral involvement was recognized, its name was changed to NSF. Subsequently, many additional cases of NSF have been identified.

All patients identified to date with NSF have had underlying renal dysfunction. Most have had stage 5 chronic kidney disease (glomerular filtration rate < 15 mL/min/1.73 m² or requirement for dialysis) and had been receiving hemodialysis. However, cases of NSF have developed in patients after successful renal transplantation, in several individuals after recovery from acute renal failure, and even in patients with lesser degrees of chronic kidney disease. Thus, although underlying kidney disease appears to be a feature common to most patients with this disease, NSF is not a complication of renal replacement therapy alone.

In 2006, after observing that five of nine patients with stage 5 chronic kidney disease who were undergoing long-term hemodialysis developed skin changes of NSF within days to weeks after receiving a gadodiamide contrast agent during MRI, Grobner proposed that NSF might result from exposure to gadolinium.⁴⁸ Subsequently, exposure to gadolinium-containing contrast agents has been demonstrated to be very strongly associated with the subsequent development of NSF among individuals with stage 5 chronic kidney disease.⁴⁹

Cutaneous features of NSF typically first involve the distal lower extremities and subsequently extend proximally.⁵⁰ Initially, patients typically report itching or burning and may notice cutaneous erythema. Some patients may have superficial skin changes in which hypopigmented, pink or flesh-colored macules or papules coalesce into patches or thin plaques, usually on the upper extremities. As the disease progresses, red to violaceous or hypopigmented fixed plaques may develop in a reticular pattern on the extremities or trunk. Dimpling of skin around hair follicles may create a peau d'orange appearance. Deep induration may develop over the upper arms, back, or thighs, creating a cobblestone-like uneven texture.

As in scleroderma, the skin on the legs and arms becomes markedly indurated so that it cannot be pinched between the thumb and forefinger, and often associated hyperpigmentation is present (Fig. 170.12). However,

Fig. 170.12 Nephrogenic systemic fibrosis.

facial involvement has not been observed in patients with NSF, and Raynaud phenomenon does not usually occur. Decreased mobility of periarticular skin typically results in fixed flexion deformities, with limited finger, elbow, and knee extension. These joint contractures may progress to compromise performance of activities of daily living and make it impossible for the patient to walk.

As more cases of NSF have appeared, prominent systemic involvement has become evident. Many patients with NSF have yellow plaques on the sclera of their eyes, nasal and temporal to the iris. Visceral fibrosis involving the heart, lungs, pleura, skeletal muscle, diaphragm, esophagus, liver, genitourinary tract, thyroid, lymph nodes, and dura mater has been identified in patients with NSF. Although often asymptomatic, visceral fibrosis may contribute to the development of cardiomyopathy, pulmonary hypertension, and skeletal muscle weakness, among other clinical manifestations.

NSF is diagnosed when characteristic clinical features are present; the diagnosis is confirmed by histologic examination of a deep skin biopsy specimen. Increased number of dermal fibroblasts is the most characteristic histologic feature of NSF. Collagen deposition is increased in the dermis, and interlobular septa and collagen bundles are surrounded by clefts. In the dermis, mucin deposition is increased and CD34+ fibrocytes, presumably originating from the circulation, are arranged in a reticular pattern or with their dendritic processes flanking intact elastic fibers. Cells of monocyte-macrophage lineage, which stain for factor XIIIa and CD68, also may be present in the dermis. Demonstration of gadolinium in tissue by inductively coupled plasma mass spectrometry provides further support for the diagnosis of NSF.

No laboratory test is diagnostic of NSF. Circulating antinuclear antibodies and antibodies to Scl-70, which are detected in many patients with scleroderma, typically are not present in patients with NSF. Circulating paraproteins, which often are present in patients with scleromyxedema, are not associated with NSF.

NSF almost always progresses relentlessly and does not usually regress spontaneously. Among patients with stage 5 chronic kidney disease, those with cutaneous changes of NSF have a threefold increased risk of dying within 2 years of the diagnosis of NSF.⁴⁹

No therapy has been demonstrated to be universally effective for the treatment of NSF. Anecdotal reports have been published of variable subjective improvement in signs and symptoms of NSF with several treatments, including sirolimus, intravenous sodium thiosulfate, plasmapheresis, ultraviolet A phototherapy, and extracorporeal photopheresis with ultraviolet A light. Treatment of several NSF patients with oral imatinib mesylate, 400 mg daily, has resulted in objective improvement in clinical measures of skin tethering and joint mobility and in the histologic appearance of fibrosis.⁵¹

Because essentially all cases of NSF have developed after exposure to a gadolinium-containing contrast agent, prevention of this devastating condition involves the careful avoidance of administration of these agents to individuals at risk. Patients with stage 4 or 5 chronic kidney disease (estimated glomerular filtration rate < 30 mL/min/1.73 m²) should not be given a gadolinium-containing contrast agent. For individuals with lesser degrees of renal dysfunction the diagnostic benefit of using a gadolinium-containing contrast agent in an imaging study must be weighed very carefully against the potential risk of the patient's developing NSF.

Use of antirheumatic drugs in patients receiving dialysis

All NSAIDs inhibit renal prostaglandin production and thus have the potential to cause reduced glomerular filtration, salt retention, and hyperkalemia, all of which may be important in dialysis patients with residual renal function. Because they are highly bound to proteins, NSAIDs are removed poorly by dialysis; postdialysis supplemental doses are unnecessary. NSAIDs are metabolized primarily by the liver; however, 40% to 95% of NSAID metabolites are excreted in the urine as glucuronide conjugates or other compounds. Because few data are available regarding the bioactivity and toxicity of these metabolites, manufacturer product labeling suggests that NSAIDs be used with caution and at reduced dosages in patients with renal failure. Patients undergoing long-term dialysis are especially susceptible to gastrointestinal bleeding, and consideration should be given to the concurrent use of a proton pump inhibitor or a prostaglandin analogue such as misoprostol when treating with NSAIDs.

The dosages of drugs used to treat gout must be adjusted in patients with chronic kidney disease. Both allopurinol and its active metabolite oxypurinol, as well as uric acid, are cleared by dialysis. Because the risk of allopurinol hypersensitivity syndrome is greater when higher doses are administered to patients with chronic kidney disease, allopurinol should be initiated at

lower doses; however, the dose should be increased cautiously to that which is adequate to achieve a lowering of serum urate level to less than 6 mg/dL.⁵² The half-life of colchicine is prolonged, and toxicity occurs more frequently in individuals with compromised renal function. Because its bioavailability is extremely variable in patients with stage 5 chronic kidney

disease and it is not cleared by dialysis, use of colchicine should be avoided. Prolonged administration of colchicine to patients with chronic kidney disease has caused a severe lysosomal, vacuolar myopathy with marked elevation of serum creatine kinase levels and, occasionally, severe heart failure.

OSTEOARTHRITIS AND
RELATED DISORDERS

171

Osteoarthritis: epidemiology
and classification

■ AMANDA E. NELSON ■ JOANNE M. JORDAN

- Osteoarthritis is the most common form of arthritis. It is strongly associated with aging and typically affects the knee, hip, spine, great toe, and hands.
- Racial and ethnic differences in frequency of osteoarthritis have been observed, with blacks more likely to have knee osteoarthritis but less likely to have hand osteoarthritis compared with whites. Hip and hand osteoarthritis are relatively rare in Chinese compared with white populations.
- Osteoarthritis can be defined by radiographs, clinical examination, or symptoms. Symptoms are more common with more severe radiographic osteoarthritis, but the association between radiographic changes and symptoms is not absolute.
- Mortality is increased in individuals with osteoarthritis compared with the general population.
- As more sensitive measures of osteoarthritis such as magnetic resonance imaging and biomarkers are developed and validated, definitions of osteoarthritis may change.

INTRODUCTION

Osteoarthritis (OA) is a condition found worldwide, is strongly associated with aging, and is the most common type of arthritis, affecting 27 million adults in the United States in 2005.¹ According to the Healthcare Cost and Utilization Project website (www.hcup-us.ahrq.gov), OA was the most common principal diagnosis for inpatient hospital stays in adults 45 to 64 years of age in 2009, with an increase of 151% in the rate of stays per 10,000 population.² Because of its effect on ambulation and mobility, OA of the knee and hip has significant functional impact and is associated with considerable medical costs, accounting for the vast majority of the 686,000 total inpatient stays for knee replacements and 438,000 total inpatient stays for hip replacements in the United States in 2009—dramatic increases from the 329,000 knee and 291,000 hip replacement inpatient stays in 1997.² Because of the aging of our society and the obesity epidemic, the burden of OA will continue to increase over the next 20 years.^{3,4}

The joint degradation in OA affects all structures in the joint and should be considered a failure of the total joint. It is characterized by thinning and fibrillation of the cartilage with loss of joint space, osteophyte formation, subchondral bony sclerosis, subchondral cysts, and deformity. The pathophysiology of OA involves not only cartilage degradation, but also changes in the subchondral bone, synovium, ligaments, tendons, meniscus, muscle, and nerve tissues. Clinically, this can be accompanied by pain on use of the

joint; stiffness, particularly after inactivity; bony enlargement and tenderness; synovial hypertrophy and effusion; limited range of motion; and decreased joint function. End-stage OA likely represents a final common pathway of a variety of conditions (e.g., inflammation, trauma, metabolic disorders) that, despite differences in etiology, lead to the same pathologic and clinical result.

OA typically affects the knees, hips, hands, spine, and feet. Classifications can differentiate between OA that is localized and OA that is “generalized,” affecting multiple joint groups. OA can also be classified as hypertrophic or atrophic, based on radiographic features of joint space narrowing or osteophytosis, and as primary or secondary to other conditions, such as metabolic disorders (e.g., ochronosis or hemochromatosis), anatomic abnormalities (e.g., slipped capital femoral epiphysis or chondrodysplasias), trauma or joint surgery, or previous inflammatory arthritis. This type of classification can be useful in clinical care and in development of inclusion and exclusion criteria for epidemiologic studies and clinical trials, but the distinctions can be artificial and ignore the more common situation of overlapping causes. The American College of Rheumatology (ACR) classification of OA is shown in [Box 171.1](#).⁵

This chapter discusses the following:

- Definitions of OA: radiographic, clinical, or symptomatic
- Prevalence of radiographic OA
- Incidence and progression of radiographic OA
- Symptomatic OA
- Mortality in OA

DEFINITIONS OF OSTEOARTHRITIS

OA can be defined pathologically, radiographically, or clinically, and the choice of definition can substantially affect prevalence estimates.⁶ The ACR criteria for the classification of OA of the hand, hip, and knee are shown in [Table 171.1](#).^{5,7,8} OA definitions for epidemiologic investigation are evolving in recognition of imperfect congruence between radiographic and clinical definitions,⁹ the variation in frequencies of and risk factors for OA in different joint sites, and new and more sensitive metrics to identify pathologic features such as magnetic resonance imaging (MRI) and biochemical markers. The presence of radiographic OA usually requires identification of a definite osteophyte with or without joint space narrowing on plain radiograph. Clinical OA is usually defined by abnormalities on physical examination consistent with OA, such as Heberden or Bouchard nodes in the hand, or limited and painful range of motion on internal rotation of the hip. Symptomatic OA is usually defined as pain, aching, or stiffness in a joint with radiographic OA. Definitions can vary according to joint site, frequency or intensity of pain, and time span over which symptoms are assessed. Definitions of incident OA and progression of OA may also vary according to joint site, individual radiographic features assessed, and the original metric used to define OA.

BOX 171.1 AMERICAN COLLEGE OF RHEUMATOLOGY CRITERIA FOR CLASSIFICATION OF OSTEOARTHRITIS

- I. Idiopathic
 - A. Localized
 1. Hands (e.g., Heberden and Bouchard nodes [nodal], erosive interphalangeal arthritis [nonnodal]): scaphometacarpal, scaphotrapezial
 2. Feet (e.g., hallux valgus, hallux rigidus, contracted toes [hammer/cock-up toes]): talonavicular
 3. Knee
 - a. Medial compartment
 - b. Lateral compartment
 - c. Patellofemoral compartment (e.g., chondromalacia)
 4. Hip
 - a. Eccentric (superior)
 - b. Concentric (axial, medial)
 - c. Diffuse (coxae senilis)
 5. Spine (particularly cervical and lumbar)
 - a. Apophyseal
 - b. Intervertebral (disk)
 - c. Spondylosis (osteophytes)
 - d. Ligamentous (hyperostosis [Forestier disease or DISH])
 6. Other single sites (e.g., shoulder, temporomandibular, sacroiliac, ankle, wrist, acromioclavicular)
 - B. Generalized: includes three or more areas listed above (Kellgren-Moore)
 1. Small (peripheral) and spine
 2. Large (central) and spine
 3. Mixed (peripheral and central) and spine
- II. Secondary
 - A. Posttraumatic
 - B. Congenital or developmental diseases
 1. Localized
 - a. Hip diseases (e.g., Legg-Calvé-Perthes, congenital hip dislocation, slipped capital femoral epiphysis, shallow acetabulum)
 - b. Mechanical and local factors (e.g., obesity [?], unequal lower extremity length, extreme valgus/varus deformity, hypermobility syndromes, scoliosis)
 2. Generalized
 - a. Bone dysplasias (e.g., epiphyseal dysplasia, spondyloapophyseal dysplasia)
 - b. Metabolic diseases (e.g., hemochromatosis, ochronosis, Gaucher disease, hemoglobinopathy, Ehlers-Danlos syndrome)
 - C. Calcium deposition disease
 1. Calcium pyrophosphate deposition disease
 2. Apatite arthropathy
 3. Destructive arthropathy (shoulder, knee)
 - D. Other bone and joint disorders (e.g., avascular necrosis, rheumatoid arthritis, gouty arthritis, septic arthritis, Paget disease, osteopetrosis, osteochondritis)
 - E. Other diseases
 1. Endocrine diseases (e.g., diabetes mellitus, acromegaly, hypothyroidism, hyperparathyroidism)
 2. Neuropathic arthropathy (Charcot joints)
 3. Miscellaneous (e.g., frostbite, Kashin-Beck disease, caisson disease)

DISH, diffuse idiopathic skeletal hyperostosis.

From Altman R, Asch E, Bloch D, et al. Development of criteria for the classification and reporting of osteoarthritis. Classification of osteoarthritis of the knee. Diagnostic and Therapeutic Criteria Committee of the American Rheumatism Association. *Arthritis Rheum* 1986;29:1039-49.

Fig. 171.1 Examples of semiquantitative radiographic assessment with use of the Kellgren-Lawrence and Osteoarthritis Research Society International (OARSI) grading schemes. (a) Kellgren-Lawrence grade 3. No lateral femoral and tibial osteophytes are seen (OARSI grade 0). A medial femoral osteophyte OARSI grade 1 (white arrow), a medial tibial osteophyte OARSI grade 2 (white arrowhead), lateral tibiofemoral joint space width OARSI grade 0, and medial tibiofemoral joint space narrowing OARSI grade 2 (black arrows) are depicted. (b) Kellgren-Lawrence grade 2. A lateral femoral osteophyte OARSI grade 2 (white arrow), a lateral tibial osteophyte OARSI grade 2 (white arrowheads), a medial femoral osteophyte OARSI grade 3 (black arrows), a medial tibial osteophyte OARSI grade 2 (black arrowhead), a normal lateral tibiofemoral joint space width OARSI grade 0, and medial tibiofemoral joint space width OARSI grade 1 (gray arrows) are shown. (From Guermazi A, Hunter DJ, Roemer FW. Plain radiography and magnetic resonance imaging diagnostics in osteoarthritis: validated staging and scoring. *J Bone Joint Surg Am* 2009;91[Suppl 1]:54-62.)

Radiographic osteoarthritis: definitions

Radiographic determination of OA has long been considered the gold standard, and multiple ways to define radiographic disease have been devised. The Kellgren-Lawrence (KL) radiographic grading scale and atlas have been in use for more than five decades. This overall joint scoring system grades OA in five levels from 0 to 4, defining OA by the presence of a definite osteophyte and more severe grades by the presumed successive appearance of joint space narrowing, sclerosis, cysts, and deformity (Table 171.2, Fig. 171.1).¹⁰ The KL scoring system has been used extensively but has been

criticized by some because of its reliance on the presence of a definite osteophyte to define a case, as well as inconsistencies in interpretation across studies.¹¹ Additionally, although individuals categorized as KL grade 1 are often classified as unaffected, these individuals likely have early OA, based on their more likely progression to higher radiographic grades over time compared to those categorized as KL grade 0.^{12,13}

Semiquantitative evaluation of individual radiographic features such as osteophytes, joint space narrowing, sclerosis, and cysts at individual joint sites can also be used.¹⁴ Direct measurement of the interbone distance as an indicator of the joint space width in the knees and hips has been proposed

TABLE 171.1
American College of Rheumatology criteria for osteoarthritis (OA) of the hand, hip, and knee

	Items required for presence of OA
Hand	
Clinical	
1. Hand pain, aching, or stiffness for most days of prior month	1, 2, 3, 4 or 1, 2, 3, 5
2. Hard tissue enlargement of ≥ 2 of 10 selected hand joints*	
3. MCP swelling in ≤ 2 joints	
4. Hard tissue enlargement of ≥ 2 DIP joints	
5. Deformity of ≥ 1 of 10 selected hand joints*	
Hip	
Clinical and radiographic	
1. Hip pain for most days of the prior month	1, 2, 3 or 1, 2, 4 or 1, 3, 4
2. ESR ≤ 20 mm/hr (laboratory)	
3. Radiographic femoral and/or acetabular osteophytes	
4. Radiographic hip joint space narrowing	
Knee	
Clinical	
1. Knee pain for most days of prior month	1, 2, 3, 4 or 1, 2, 5 or 1, 4, 5
2. Crepitus on active joint motion	
3. Morning stiffness ≤ 30 min in duration	
4. Age ≥ 38 yr	
5. Bony enlargement of the knee on examination	
Clinical and radiographic	
1. Knee pain for most days of prior month	1, 2 or 1, 3, 5, 6 or 1, 4, 5, 6
2. Osteophytes at joint margins (radiograph)	
3. Synovial fluid typical of OA (laboratory)	
4. Age ≥ 40 yr	
5. Morning stiffness ≤ 30 min in duration	
6. Crepitus on active joint motion	

*Ten selected hand joints include bilateral second and third proximal interphalangeal joints, second and third distal interphalangeal joints, and first carpometacarpal joints. DIP, distal interphalangeal; ESR, erythrocyte sedimentation rate; MCP, metacarpophalangeal. From Altman R, Asch E, Blach D, et al. Development of criteria for the classification and reporting of osteoarthritis. Classification of osteoarthritis of the knee. *Diagnostic and Therapeutic Criteria Committee of the American Rheumatism Association. TABLE 171.2
Kellgren-Lawrence radiographic grading system for osteoarthritis

Grade	Classification	Description
0	Normal	No features of osteoarthritis
1	Doubtful	Minute osteophyte, doubtful significance
2	Minimal	Definite osteophyte, unimpaired joint space
3	Moderate	Moderate diminution of joint space
4	Severe	Joint space greatly impaired with sclerosis of subchondral bone

Adapted from Kellgren JH, Lawrence JS, editors. *The epidemiology of chronic rheumatism, atlas of standard radiographs*. Oxford: Blackwell Scientific; 1963.

as a more powerful tool to define OA and to investigate progression in epidemiologic studies and clinical trials of disease-modifying therapies.^{15,16} Standardized protocols for radiographic image acquisition and methods for scoring have been devised that show good reliability, and use of digitized images and computer scoring can decrease error.¹⁷ However, the sensitivity of these metrics in demonstrating change over time and effect of therapeutic interventions is limited, and more functional and dynamic imaging metrics are under evaluation. These issues are discussed further in Chapters 177 and 180.

Studies have compared several of these scoring systems in measuring prevalence of radiographic OA and its association with symptoms and other OA outcomes. Composite definitions accounting for both osteophytes and joint space narrowing are most strongly associated with hip pain and later total hip replacement.^{18,19} A recent study of hand OA found independent associations between osteophytes and joint space narrowing and hand joint pain.²⁰ Neogi and colleagues,²¹ after controlling for confounding by examining knee pain and radiographic OA features *within individuals* with knees discordant for pain, found strong correlations between radiographic measures (KL grade, osteophytes, or joint space narrowing) and pain.

Prevalence of radiographic osteoarthritis

Although OA affects individuals worldwide, some geographic variation in disease does exist and can inform investigations into etiology and pathogenesis. The following discussion includes data on radiographic OA of the hip, knee, and hand, with a mention of other sites that have been less well characterized.

Prevalence of radiographic hip osteoarthritis

The overall prevalence of radiographic hip OA varies widely, from less than 1% to 27%, depending on the population being studied.²² Although early studies reported low rates of hip OA in African and Caribbean blacks²³ and lower rates of hip replacement in blacks than in whites,²⁴ more recent evidence from population-based studies shows that blacks and whites in the United States have a similar prevalence of hip OA.^{25,26} The first National Health and Nutrition Examination Survey (NHANES I), conducted from 1971 to 1975, reported no difference in the prevalence of hip OA, defined by KL grade, between blacks and whites.²⁵ The Johnston County Osteoarthritis Project reported a similar prevalence of radiographic hip OA (defined as a KL grade of 2 or higher) among whites (27%) and blacks (32%); frequencies of severe radiographic hip OA (KL grade 3 or 4) were also similar (2.4% in whites and 3.1% in blacks).²⁶ Hip OA was 80% to 90% less frequent in Chinese individuals than in whites in a study using standardized methods and the same readers for all radiographs.²⁷ The prevalence of radiographic hip OA, defined as a minimal joint space of 2.5 mm or less, is higher in Iceland, present in about 8% of those aged 35 years or older, compared with 1.2% in South Sweden; a strong genetic component is felt to be responsible for this difference.²⁸

Prevalence of radiographic knee osteoarthritis

A subset of individuals aged 60 years and older participating in NHANES III (1991 to 1994) had an overall prevalence of radiographic knee OA of 37%, higher than estimates from NHANES I, and higher in blacks (52%) than in Mexican Americans (40%) or non-Hispanic whites (36%).²⁹ Other U.S. studies have examined the prevalence of radiographic knee OA with some variation in results, perhaps based on cohort effects and differences in study design, radiographic reading protocols, and population studied. Radiographic knee OA was present in 33% of men and 42% of women in the original cohort of the Framingham Osteoarthritis Study (1983 to 1985), without substantial change at follow-up (1992 to 1995; Fig. 171.2).³⁰ Twenty-eight percent of participants in the Johnston County Osteoarthritis Project aged 45 years and older had radiographic knee OA, with slightly more blacks affected than whites.³¹

In the Beijing Osteoarthritis Study, radiographic knee OA was more common in Chinese women than in white women from Framingham, despite a lower body mass index (BMI) among the Chinese women.³² The Copenhagen Osteoarthritis Study (1992 to 1994) found a relatively low prevalence of radiographic knee OA of 12% for men and 14% for women, which was partially explained by a low BMI (mean, 26 kg/m²) in that group.³³

Many studies of radiographic knee OA are limited to the tibiofemoral joint and therefore underestimate the prevalence of radiographic knee OA and symptomatic knee OA by omitting the patellofemoral joint. Much of patellofemoral joint OA coexists with tibiofemoral OA, but it can exist as an isolated phenomenon in up to about 13% of individuals, particularly in younger populations,³⁴ has been associated with significant pain and disability, and may have unique biomechanical or other risk factors.³⁵

INCREASING PREVALENCE OF KNEE PAIN AND SYMPTOMATIC KNEE OSTEOARTHRITIS: SURVEY AND COHORT DATA

Fig. 171.2 Age- and body mass index (BMI)-adjusted prevalence of radiographic and symptomatic knee osteoarthritis (OA) in participants in the Framingham Osteoarthritis Study across three examination periods. Error bars represent 95% confidence intervals. For radiographic knee OA (Kellgren-Lawrence grade of 2 or higher), test for trend from 1983 to 2005: $P = .82$ (men) and $P = .04$ (women). For symptomatic knee OA (knee pain in the knee with radiographic OA), test for trend from 1983 to 2005: $P < .001$ (men) and $P = .006$ (women). (From Nguyen UDT, Zhang Y, Zhu Y, et al. Increasing prevalence of knee pain and symptomatic knee osteoarthritis: survey and cohort data. *Ann Intern Med* 2011;155:725-32.)

Prevalence of radiographic hand osteoarthritis

Radiographic hand OA is usually defined as a KL grade of 2 or higher in specific joints, namely, the distal interphalangeal (DIP) joints, the proximal interphalangeal (PIP) joints, and the carpometacarpal (CMC) joints or thumb base. Involvement of the metacarpophalangeal (MCP) joints has received less study. Criteria for case definitions may include the presence of radiographic hand OA in any hand joint or in a selected subset of hand joint sites, usually including the DIPs, PIPs, and CMCs.⁷ Radiographic hand OA is extraordinarily common, particularly in older age groups. The Framingham Osteoarthritis Study observed radiographic OA in 22.1% of hand joints of older men and in 32.7% of hand joints of older women.³⁶

Radiographic hand OA involving any hand joint was present in 25.5% of black women and 19.2% of white women in the Southeast Michigan cohort of perimenopausal women.³⁷ The Rotterdam study reported that 67% of women and 55% of men aged 55 years and older had radiographic hand OA in at least one joint and 28% had radiographic hand OA in at least two of three hand joint sites (DIP, PIP, CMC).³⁸ The age-specific frequency of involvement of hand joint groups in this study is displayed in Figure 171.3. Radiographic hand OA is relatively uncommon in Chinese and Japanese adults.^{39,40}

Prevalence of radiographic osteoarthritis in other sites

OA in other common sites such as the spine and first metatarsophalangeal joints is less well studied. The Framingham Heart Study showed a high prevalence of facet joint OA (60% in men and 67% in women) by computed tomographic imaging, although no association with pain was identified.⁴¹ Degenerative disk disease of the lumbosacral spine is also extremely common, with anterior osteophytes and disk space narrowing present in 91% and 68%, respectively, in one population-based study of women,⁴² and in 88% and 58% in a cross-sectional study including African American and white men and women⁴³; whether degenerative disk disease represents spinal OA remains controversial. OA of the joints of the feet is also common but understudied; one estimate reported a prevalence of 42% in the first metatarsophalangeal joint in an elderly population with a high prevalence of OA at other joints.⁴⁴

AGE-SPECIFIC FREQUENCY OF INVOLVEMENT OF HAND JOINT GROUPS WITH RADIOGRAPHIC OA

Fig. 171.3 Prevalence (in percent) of radiographic osteoarthritis (OA) (Kellgren-Lawrence grade of 2 or higher) affecting various hand joint groups in different ages cohorts in the Rotterdam study. CMC1, first carpometacarpal joint; DIPs, distal interphalangeal joints; MCPs, metacarpal phalangeal joints; PIPs, proximal interphalangeal joints; TS, trapezioscapoid joint. (From Dahaghin S, Bierma-Zeinstra SM, Ginai AZ, et al. Prevalence and pattern of radiographic hand osteoarthritis and association with pain and disability [the Rotterdam study]. *Ann Rheum Dis* 2005;64:682-7.)

Incidence and progression of radiographic osteoarthritis: definitions

Incidence and progression of radiographic OA are defined separately for individual joint groups and, increasingly, for the individual radiographic features of osteophytes and joint space narrowing or their combination.

Development of KL grade 2 or higher from a baseline of 0 or 1 can be used to define incident hip OA; other definitions using algorithms such as the Croft scale or the development of a minimum joint space of 2.5 mm or less consider the presence of specific radiographic features. In the Rotterdam study, after a mean follow-up of 6.6 years, incident hip OA was identified in 3.9% of 5481 hips with KL grade 1 or less at baseline.⁴⁵ Beattie and colleagues,⁴⁶ in a study of statin use and hip OA using data from the Study of Osteoporotic Fractures, reported development of incident OA in 566 of 4933 older white women who did not have OA at the baseline evaluation 8 years earlier (11% incidence) based on a composite definition. Arden and colleagues¹⁸ have reported that composite definitions based on the presence of more than one individual radiographic feature had the strongest associations with pain and future need for hip replacement and recommended the use of such composites to define incident hip OA in epidemiologic studies.

Progression of hip OA in the Study of Osteoporotic Fractures over 8 years was defined by an increase in the summary radiographic grade, increase in total osteophyte score, decrease in minimal joint space of at least 0.5 mm, total hip replacement, or increase in lower-extremity disability score.⁴⁷ Sixty-five percent of hips with radiographic OA at baseline demonstrated radiographic progression by these criteria, with risk of progression higher in those with hip symptoms at baseline. In contrast, a study of individuals undergoing colon radiography in Iceland found that fewer than 3% of normal hips later required hip replacement, compared with 17% of hips with baseline hip OA, defined as a minimum joint space of 2.5 mm; these data suggest a lower rate of progression, although differences in methods and population make direct comparisons difficult.⁴⁸

For radiographic knee OA, incidence is commonly defined as the development of KL grade 2 or higher from a baseline grade of 0 or 1, or alternatively by the development of a definite osteophyte. Felson and colleagues⁴⁹ reported that 15.6% of elderly Framingham study participants developed incident radiographic knee OA over an 8-year follow-up period, with women at higher risk than men. More recently, the Chingford study of older white women reported an annual cumulative incidence of radiographic knee OA of 2.3% over 14 years, or a total incidence of 39.5%.¹³

Progression of radiographic knee OA can be defined as an increase in KL grade in those with prevalent radiographic knee OA at baseline. In such analyses, those with KL grade 4 cannot progress, except to joint replacement. Alternatively, progression could also include an increase in the grade of semiquantitatively defined osteophytes or joint space narrowing. LaValley and colleagues⁵⁰ found that definitions incorporating both osteophytes and joint space narrowing, rather than ordinal assessment of joint space narrowing alone, yielded the most precise estimates of radiographic knee OA worsening in relationship to known risk factors. Quantitative determination of changes in minimum joint space width is the only U.S. Food and Drug Administration–accepted structural outcome measure for clinical trials of disease-modifying OA drugs and is the most frequently used measure in the clinical trial setting.⁵¹

New MRI measures are being developed and validated and will require updated definitions of OA incidence and progression.⁵² MRI technology allows assessment of not only bone but also articular cartilage, menisci, osteophytes, subchondral bone, and ligamentous and synovial structures using both qualitative and quantitative methods. Semiquantitative scoring systems encompassing many of these features have been developed for the knee, although issues such as optimal sequence and image quality, time for scoring, and necessary reader expertise and training have yet to be fully addressed.⁵³ It also remains unclear what constitutes a pathologic lesion versus an incidental finding because of the high sensitivity of MRI.⁵⁴ MRI is attractive as a new standard measure in knee OA, but barriers such as high cost to obtain and operate the equipment, length of time required for acquiring and interpreting the images, and contraindications to the procedure have limited its use in most large longitudinal cohort studies, although that has begun to change with the Osteoarthritis Initiative.⁵⁵ However, MRI may well be the modality of choice in future clinical trials of structure-modifying drugs and epidemiologic studies, provided its reach can be extended beyond tertiary research centers (see Chapter 177).

Symptomatic osteoarthritis: definitions

Although the likelihood of symptoms, variously defined as pain, aching, and stiffness, is higher with more severe radiographic grades of OA, it has long been recognized that there is a lack of perfect congruence between radiographic findings of OA and clinical symptoms.⁹ Up to 60% of individuals with radiographic knee OA may not complain of pain. However, recent studies using novel methods to control for confounding have suggested a closer relationship between radiographic findings and symptoms.²¹ Additionally, individuals with radiographic knee OA but without frequent pain may still have quadriceps weakness^{55,56} and have a higher likelihood of disability or dependence on others to perform tasks of daily living.⁵⁷ This suggests that individuals may curtail symptom-inducing activities and that even “asymptomatic” radiographic OA is not without consequence.

Nonetheless, in recognition that OA associated with symptoms and disability is more significant in determining the need for medical care and services than asymptomatic OA, epidemiologic definitions of OA that incorporate symptoms and impact are of increasing importance. Symptomatic OA is usually defined as the presence of symptoms in a joint with radiographic OA. Incidence of symptomatic OA would be defined as the development of radiographic OA in someone with symptoms, the development of symptoms in someone with radiographic OA, or the development of both symptoms and radiographic OA in someone without either at baseline. Progression of symptomatic OA would involve progression of either radiographic OA or symptom severity or both.

Another potential definition of symptomatic knee and hip OA progression not captured in these definitions is joint failure leading to total joint replacement. Because many factors such as country of residence, health care system factors, demographic factors, comorbidities, willingness to undergo surgery, and psychological factors influence the receipt of a joint replacement, perhaps a more appropriate metric in this regard would be progression leading to the need for total joint replacement; how this would be defined for research and policy purposes is currently the subject of considerable attention in the epidemiologic research community.⁵⁸ A summary of prevalence estimates for symptomatic OA in the hands, knees, and hips is presented in Table 171.3.

Prevalence of symptomatic hip osteoarthritis

Exact figures for the prevalence of symptomatic hip OA in the population are difficult to derive from studies in the literature to date. In the Rotterdam study, OA of KL grade 2 or higher in the hip was present in 7.8% of men and 6.4% of women. Among those with a radiographic KL grade of 2 or higher, 2.1% of men younger than the median of 65.2 years reported hip pain, and 17% of older men, 36% of younger women, and 32% of older

TABLE 171.3

Prevalence of symptomatic osteoarthritis (OA) in the hands, knees, and hips from population-based studies*

Anatomic site, age (yr)	Study	% with symptomatic OA		
		Male	Female	Total
Hands, ≥26	Framingham OA study	3.8	9.2	6.8
Knees				
≥26	Framingham OA study	4.6	4.9	4.9
≥45	Framingham OA study	5.9	7.2	6.7
≥45	Johnston County OA project	13.5	18.7	16.7
≥60	NHANES III	10.0	13.6	12.1
Hips, ≥45	Johnston County OA project	8.7	9.3	9.2

*Adjusted to the projected 2000 population age ≥8 yr except for NHANES III estimates, which were adjusted to the 1980 census population.

NHANES III, National Health and Nutrition Examination Survey III; OA, osteoarthritis.

From Lawrence RC, Felson DT, Helmick CG, et al. Estimates of the prevalence of arthritis and other rheumatic conditions in the United States. Part II. *Arthritis Rheum* 2008;58:26-35.

women reported hip pain.⁵⁹ A French study of individuals aged 40 to 75 years conducted from 2007 to 2009 reported an overall prevalence of symptomatic hip OA of 1.9% among men and 2.5% among women, with higher frequencies in older age groups.⁶⁰ The Johnston County Osteoarthritis Project identified hip symptoms in 36% of the nearly 3000 individuals studied, with 10% meeting criteria for symptomatic hip OA (defined as the presence of symptoms in a hip with KL grade 2 or higher).²⁶ The frequency of symptomatic hip OA was higher in women and blacks and increased with age.²⁶ As was found in studies of radiographic hip OA, symptomatic hip OA is infrequent in Chinese individuals, with frequencies ranging from 0.03% to 2% in five different studies.⁶¹

Prevalence of symptomatic knee osteoarthritis

The prevalence of symptoms in those with radiographic knee OA varies depending on definitions of radiographic OA, definitions of pain and symptoms, and population studied. Based on data from NHANES III, the prevalence of symptomatic knee OA is estimated to be 12% in adults 60 years old and older.²⁹ The Framingham Osteoarthritis Study found that 9.5% of persons aged 63 to 93 had symptomatic knee OA; prevalence was higher in women (11.4%) than in men (6.8%).⁶² A more recent estimate of the prevalence of symptomatic knee OA in adults aged 45 years and older, reported by the Johnston County Osteoarthritis Project, was 16%.³¹ Nguyen and colleagues³⁰, examining Framingham data for 1983 to 2005, reported a substantial increase in both age- and BMI-adjusted knee symptoms (in women, from 16% to 33%; in men, from 9% to 28%) and symptomatic knee OA (in women, from 10% to 17%; in men, from 6% to 16%) over 20 years despite the lack of any significant change in radiographic OA prevalence (see Fig. 171.2).

Whereas reduced joint space width in the hip has been associated with hip pain,¹⁹ osteophytes may have a larger role in knee pain. Lanyon and colleagues⁶³ reported that the presence of osteophytes was more strongly associated with pain than was joint space narrowing. Stronger associations between knee pain and osteophytes have been shown in individuals with both tibiofemoral and patellofemoral osteophytes than in those with osteophytes in either compartment alone.⁶⁴ However, a study using a within-person knee-matched design reported that although both joint space narrowing and osteophytes were associated with pain, the magnitude of the association was higher for joint space narrowing.²¹ Multiple features on MRI have also been associated with knee pain. Bone marrow lesions, particularly when large, are strongly related to knee pain, whereas synovitis and effusion are moderately associated. Weak relationships have been seen between pain and cartilage volume or thickness, and no consistent association exists between meniscal tears and pain.⁶⁵

Prevalence of symptomatic hand osteoarthritis

Radiographic OA in at least one hand joint is almost universally present in older age groups, but not all is symptomatic. Symptoms may be in the hand in general or in any joint of a specific hand joint group; the CMC joint may contribute more strongly to hand symptoms than other hand joints.⁶⁶ Symptomatic hand OA, with pain in a specific hand joint on most days and radiographic OA in that same joint, was present in 16% of older women in the Framingham cohort and 8% of men (age-standardized estimates were 14% for women and 7% for men), the thumb base and DIP joints were most

Fig. 171.4 Incidence of symptomatic osteoarthritis (OA) of the hand, knee, and hip as a function of age. (Data from Fallon Community Health Plan; Oliveria SA, Felson DT, Reed JL, et al. Incidence of symptomatic hand, hip, and knee osteoarthritis among patients in a health maintenance organization. *Arthritis Rheum* 1995;38:1134-41.)

frequently involved.⁶⁷ In the Rotterdam study, in which the frequency of radiographic hand OA was more than 60%, the frequency of hand pain was 14%, with slightly stronger associations with the most severe radiographic grades and with the number of joints affected with OA.³⁸ Dillon and colleagues,⁶⁸ using data from NHANES III, reported a prevalence of 8% for symptomatic hand OA, defined according to ACR clinical criteria; they estimated that 1 in 12 older adults in the United States may be affected by symptomatic hand OA.

Incidence and progression of symptomatic osteoarthritis

Longitudinal studies of incident symptomatic OA in the community are few and are often done using large administrative databases, which have inherent limitations including diagnostic and coding errors. Oliveria and colleagues⁶⁹ reported age- and sex-standardized incidence rates of symptomatic hip, knee, and hand OA of 88, 240, and 100 per 100,000 person-years, respectively, in participants in a Massachusetts health maintenance organization (Fig. 171.4). Kopec and colleagues,⁷⁰ using an administrative database in British Columbia, Canada, reported trends in standardized incidence rates for OA in any joint site over an 8-year period (Fig. 171.5). A study using a military database to assess incident hip OA found an overall incidence rate of 35 cases per 100,000 person-years, with higher rates among women and blacks (54 cases per 100,000 person-years for women, and 51 cases per 100,000 person-years for blacks).⁷¹

Progression of symptomatic OA is also understudied, despite its significant impact. In the Study of Osteoporotic Fractures, of approximately 6000 women followed over 8 years, 12.6% had radiographic hip OA at baseline, with almost half of cases symptomatic. At follow-up, almost a quarter of hips with symptomatic OA at baseline had progressed to total joint replacement.⁴⁷ A different way of assessing the burden of symptomatic OA is by considering the lifetime risk, which represents the probability of developing the condition over the course of a lifetime. Using data from the Johnston County Osteoarthritis Project, Murphy and colleagues⁷² reported a lifetime risk of symptomatic knee OA of 45%, with higher risk in those with prior injury and in obese individuals. The lifetime risk of symptomatic hip OA was 27% and was higher in women than in men (31% and 20%, respectively).⁷³ A UK study estimated the lifetime risk of total joint replacement

Fig. 171.5 Incidence rates of osteoarthritis in British Columbia, Canada, from 1996-1997 to 2003-2004 for men (a) and women (b) of various ages. (From Kopec JA, Rahman MM, Sayre EC, et al. Trends in physician-diagnosed osteoarthritis incidence in an administrative database in British Columbia, Canada, 1996-1997 through 2003-2004. *Arthritis Rheum* 2008;59:929-34. Reprinted with permission of John Wiley & Sons.)

at the knee (11% for women and 8% for men) and hip (12% for women and 7% for men),⁷⁴ revealing a substantial difference between estimates for symptomatic OA and for “end-stage” OA, although comparisons are complicated by the impact of numerous factors that affect the decision to undergo joint replacement. Assessment of incidence and progression of symptomatic OA is another area that will likely benefit from the increasing use of MRI, because this modality provides a greater sensitivity to change compared with conventional radiography.⁵²

MORTALITY IN OSTEOARTHRITIS

Hochberg⁷⁵ published a systematic review that revealed moderate evidence of increased mortality in individuals with OA compared with the general population. One study showed an increased mortality risk with increasing numbers of joint groups affected by OA, as well as reduced survival in individuals with hand, bilateral knee, or cervical spine involvement, but not in those with hip, foot, or lumbar spine involvement.⁷⁶ This modestly increased mortality risk, determined through a review of nine studies, appeared to be due primarily to cardiovascular and gastrointestinal causes.⁷⁵ A study published since that review confirms excess all-cause mortality in OA patients (defined as those having a KL grade of at least 1 in at least one knee or hip) compared with the general population (standardized mortality

ratio [SMR], 1.55; 95% confidence interval, 1.41 to 1.70); the excess risk was particularly notable for cardiovascular mortality (SMR, 1.71) and dementia-related mortality (SMR, 1.99).⁷⁷ Higher mortality was associated with increasing age, male sex, walking disability, and self-reported comorbidities (diabetes, cancer, cardiovascular disease) but not with joint affected, previous joint replacement, obesity, nonsteroidal antiinflammatory drug use, depression, or baseline hip or knee pain. The authors hypothesize that reduced physical activity and a chronic inflammatory state in OA patients may contribute and should be aggressively managed.⁷⁷

Local and systemic risk factors for incidence and progression of osteoarthritis

■ DAVID T. FELSON ■ YUQING ZHANG

- Osteoarthritis is caused by a combination of systemic factors and factors in the local joint environment. The systemic factors such as aging cause joints to be vulnerable to acute or repetitive injury.
- Osteoarthritis is mechanically driven, and factors that increase focal loading (stress) across the joint increase the risk of disease incidence and progression. For knees, this is varus/valgus malalignment, and for hips, the most common cause is abnormal joint shape, which often develops in childhood.
- In the knee, obesity and previous major joint injuries such as a meniscal tear are powerful risk factors for disease, but the etiologic roles of physical activity and muscle weakness across the knee are less clear.
- Because knees and hips with osteoarthritis all have risk factors for disease, they also all have risk factors for disease progression. Therefore identifying risk factors for progression is very difficult, whereas risk factors for new-onset (incident) disease can be identified readily.

INTRODUCTION

An appreciation of risk factors that lead to osteoarthritis (OA) may provide insights not only into disease pathogenesis but also into opportunities for disease prevention and treatment. This chapter focuses on risk factors for OA of the knee, hip, and hand, the structures most commonly affected by symptomatic disease. Since most studies have focused on OA of the knee, the joint whose involvement is most commonly disabling, the majority of this review covers knee studies. Furthermore, the chapter focuses primarily on risk factors for incidence on the assumption that they also affect risk of progression. The one exception is malalignment, which is a stronger risk factor for progression than incidence. When there are specific relevant risk factors for hip or hand OA, these are discussed.

THE CHALLENGE OF STUDYING INCIDENCE VERSUS PROGRESSION IN OSTEOARTHRITIS

Epidemiologists generally distinguish between the new onset of disease (incidence) and worsening of disease in persons who already have it (progression). In OA this distinction is generally applied to radiographic disease, in which incident disease is defined in persons who initially have no radiographic disease and then develop it. Individuals who already have radiographic disease are followed for disease progression. Natural history studies and clinical trials focus almost solely on disease progression because subjects with clinical symptoms usually have radiographic OA.

Although the distinction between incidence and progression has been useful for OA research, any distinction is artificial, because there is no clearcut time when disease suddenly occurs. OA is an evolving disease of insidious onset. Structural changes and symptoms often do not occur suddenly but rather develop gradually, from mild and occasional to worse and persistent. Any threshold beyond which a person is labeled as having disease divides a continuum of both structural change and pain evolution into categories that are, to some extent, artificial. Further, depending on the

particular radiographic feature and the definition of pain that constitutes the threshold, OA may be defined differently by different investigators in different studies.

THE DISCORDANCE BETWEEN RADIOGRAPHIC OSTEOARTHRITIS AND JOINT PAIN

Many persons with radiographic disease have little if any joint pain, and many persons with joint pain do not have radiographic OA. Further, the radiographic changes of OA occur fairly late in the development of disease. What is most important from a clinical and public health perspective is joint pain, which causes suffering and disability. Even though there is a discordance between radiographic disease and joint pain, radiographic knee OA is a very strong risk factor for knee pain (e.g., those with Kellgren-Lawrence grade III OA in the knee have a ninefold risk of knee pain compared with those who have grade 0 OA).¹

Because the literature on risk factors for OA contains a mixture of studies of radiographic disease (most studies) and studies of symptomatic disease, this chapter mixes them also. There is no evidence yet that specific risk factors affect pain and not structural disease represented by radiographs, although for some risk factors such as muscle weakness, there appears to be a much stronger relation with symptoms than with structure.

A FRAMEWORK FOR UNDERSTANDING SYSTEMIC AND LOCAL RISK FACTORS FOR OSTEOARTHRITIS

As shown in Fig. 172.1, OA is caused by a combination of systemic factors and factors in the local joint environment. Many systemic factors may cause disease by affecting the vulnerability of the joint within the local environment (e.g., muscle weakness, neurologic response times). Because they operate on all joints that might be vulnerable to OA, systemic factors are conceived as having systemic effects, but the mechanisms underlying their effects on specific joints are in fact local.

Systemic risk factors

As reviewed in the previous chapter, OA occurs primarily as people get older. Changes in the joint environment with aging have a combined effect on the joint, making it vulnerable to the development of OA. Cartilage gets thinner with age. This may increase the laxity of the joint, making it more vulnerable to injury and it increases cartilage susceptibility to shear stress at the basal levels where cartilage attaches to bone. Early lesions of cartilage damage² show clefts at this basal level suggesting shear-stress damage. With age, chondrocytes, which do not replicate throughout life, become senescent and become less responsive to regulatory growth factors in the cartilage matrix environment,³ and the cartilage matrix itself changes in ways that make it more vulnerable to injury.

The local joint environment also changes with age in ways that make the joint susceptible to damage. With age, muscles become weaker and less well conditioned. Reaction times slow so that incipient injury to a joint from an oncoming weight-bearing load may not be buffered or shock absorbed as competently in an older joint as in a younger one. Aging assumes such a major place as a risk factor for OA because, in aging, more than one of these factors operates at the same time to increase disease risk.

Fig. 172.1 Systemic risk factors can act both systemically and, more often, by affecting elements of the local joint environment that increase susceptibility of the joint to osteoarthritis. ACL, anterior cruciate ligament.

Much less well understood is the increase in OA risk that occurs in women compared with men, especially in women after menopause. Some of the changes in local joint environment may be more prominent in women (e.g., loss in strength and conditioning), and hormone-related changes that occur in postmenopausal women may increase disease risk, although the data on estrogen loss and its relation to the development of OA are mixed.⁴

The relation of systemic factors such as genetic and ethnic predisposition are covered elsewhere in this section, but like other systemic factors, it is likely that these operate by making the local joint environment more vulnerable to disease.

Another set of systemic factors that may influence the risk of disease are nutritional deficiencies. For a number of vitamin and other micronutrient deficiencies, there is now conflicting evidence on their association with disease. For example, vitamin D deficiency was tied to progressive knee OA in one study⁵ and incident hip OA in another,⁶ but subsequent studies of knee OA have shown no association of vitamin D deficiency with disease risk.⁷ Despite one report suggesting that vitamin E deficiency may be related to OA progression risk,⁸ trials testing vitamin E supplementation showed no effect on OA.⁹

Even if it does not have direct effects on joint structure, vitamin D deficiency may have indirect effects on joint health by lowering the threshold for joint pain. Vitamin D deficiency has been linked with generalized pain, and vitamin D deficiency may impair muscle function so that rehabilitation is difficult and conditioning impeded in those affected, which could in turn affect the course of knee OA in that person.

Vitamin K deficiency due to inadequate intake of cruciferous vegetables is common in older people. Vitamin K is a critical cofactor involved in enzymes that are active metabolically in both cartilage and bone, and its deficiency may impair the actions of these enzymes, making cartilage and underlying bone vulnerable. In one large study, vitamin K deficiency was associated with hand and to a lesser extent knee OA,¹⁰ and results of a limited clinical trial in hand OA,¹¹ although not formally positive, suggested in subgroups in whom vitamin K deficiency was corrected by supplementation that joint space loss was prevented. A more definitive study of the effect of vitamin K on OA is needed.

That systemic predilection is an important element of OA risk stems from studies showing that a person with OA in one joint is at high risk of getting it in others, even other joints distant from the first. For example, those with hand OA have a high risk of getting knee or hip OA,¹² and persons with meniscal tears, already at high risk of knee OA, are at even higher risk if they have hand OA.

Factors in the local joint environment

The physiologic distribution of load across a joint conforms with normal joint anatomy when the joint is healthy. For example, the medial

Fig. 172.2 With normal alignment (left), loading occurs physiologically. With early medial disease (right), there is a tilting of the joint so that focal load (stress) increases medially (curved line with two arrowheads), which leads to further focal medial load. A vicious cycle of increased medial joint damage, more tilting, and further increased medial stress develops.

compartment of the knee is designed to carry more load than the lateral compartment based on its larger size and concave-convex tibiofemoral condylar shape. In all joints, cartilage and other structures in the joint are designed to bear a certain amount of stress (force per unit area) during loading and joint use. When the direction of the transarticular load changes or when the joint becomes misshapen, altering loading patterns inside the joint, focal loads within the joint transcend physiologic parameters and joint damage can occur. This damage usually occurs focally at the site of excess load. For example, when the knee becomes varus malaligned (bowlegged), excess load is transmitted through the medial compartment of the knee, and areas within the medial compartment experience a heightened risk of cartilage loss and bony change. Such changes can be induced in rabbits just by putting a spring across the proximal and distal medial knee compartment, which increases load medially.

In the hip, abnormal joint shapes may develop during childhood but may not be clinically manifest until adult years because the excess loads conferred by these abnormal joint shapes are tolerated until adult years when compensatory joint-protective mechanisms do not work as well. Any combination of different directions of load or abnormal focal stresses because of abnormal joint shape accelerates the development and progression of OA and can constitute one of the strongest risk factors for disease.

OA is a mechanically driven disease, and one of the key contributors to loading in the knees is malalignment in the frontal plane (varus or valgus). In nonosteoarthritic knees, there is usually at most a trivial degree of malalignment, since malalignment develops as a consequence of disease.¹³ As disease develops, focal involvement within the joint (e.g., focal cartilage loss or meniscal extrusion) leads the knee to tilt and bony remodeling occurs, with the knee becoming increasingly malaligned (Fig. 172.2); with a little bit of varus malalignment comes increasing medial loading and more damage to the medial side of the knee, which leads to yet more tilting of the joint and more malalignment. The same is true of valgus malalignment.¹⁴ In this way, malalignment may contribute to a vicious cycle of focal joint damage leading to increased focal stress and further joint damage.

The direction of loading across the knee is determined by the origin and direction of pull of the muscles that move the joint; for the knee, the proximal origin is around the hip joint and the distal origin, the ankle. Thus the mechanical axis around the knee is determined by a line from the femoral head to the knee (the femoral mechanical axis) and the angle it forms with a line drawn from the ankle to the knee (the tibial mechanical axis). Full-limb radiographs that assess the mechanical axis from the hip to the knee and from the knee to the ankle are the ideal measure of standing

malalignment. The knee radiographs contain images of only the distal femoral and proximal tibial shafts and where they intersect in the knee, and a measure of this angle (the anatomic axis), despite its being correlated with the mechanical axis, is an imperfect substitute for measurement of the mechanical axis.¹⁵ Although it is easy to assess malalignment on a radiograph, the radiograph measures malalignment only in one static position. The optimal way to assess medial-lateral alignment across the knee is during walking, so-called dynamic alignment. A key measure of medial load is the adduction moment, an estimate of the load across the medial compartment of the knee during walking.¹⁶ High adduction moments are a feature of medial knee OA and markedly increase the risk of further medial disease progression.¹⁷ Limbs with varus mechanical axes are at high risk of progression of medial knee OA,^{18,19} either measured as later medial joint space loss on radiography or medial cartilage loss on magnetic resonance imaging (MRI).²⁰ and valgus limbs have an increased risk of lateral joint space loss and commensurate cartilage loss. In knees without OA, malalignment is also a risk factor for disease incidence.^{14,21}

Because varus malalignment is extremely common in advanced OA, it is sometimes not clear conceptually whether it simply represents one element of disease occurrence or should be regarded as a risk factor. The truth is that it is both, but its presence in severe disease makes it difficult to disentangle whether severe disease propels progression by itself or whether it does so only in the face of malalignment. Regardless, malalignment, when present, is such a potent risk factor for disease progression in knee OA that other known risk factors assume less prominence when compared to it. For example, obesity is a potent risk factor for the new onset of knee OA, but in knees with established disease, obesity's effect on progression varies depending on the limb's alignment.¹³ Only in neutrally aligned knees is there an effect of obesity on disease progression.²² In knees with disease and varus malalignment, obesity has no effect on the risk of progression, which suggests that the effects of malalignment are dominant. This potent effect of malalignment constitutes one major reason why risk factors for progression of knee OA have been hard to identify.

Previous joint injury

In some joints such as the ankle and the wrist, which are only rarely affected by OA, most disease is caused by major joint injury.²³ For example, a plafond fracture of the ankle causes inevitable OA. In joints more commonly affected by OA such as the knee and hip, major joint injuries, perhaps even unrecognized ones, also are likely to be major causes of disease. Even though such injuries originate outside the joint, they are placed in the category of local joint environmental factors because they ultimately alter the joint environment in ways that dictate what happens to the joint. In the knees, the common joint injuries with important effects on subsequent joint function and disease are anterior cruciate ligament (ACL) tears and meniscal tears.

ACL tear is increasingly common in young athletes, especially girls. Jumping and landing with an internally rotated femur is a major precipitant of tearing of the ACL, an injury that is often accompanied by other internal derangements such as meniscal and medial collateral ligament tears. The risk of knee OA after an ACL tear differs greatly depending on whether the meniscus or other structures in the knee were damaged at the time of the injury. Isolated ACL tears may pose only a modest risk of later knee OA (0% to 13% at a longer than 10-year follow-up).²⁴ Graft surgeries to repair the ACL or reconstitute the ACL do not decrease the risk of later knee OA, in part because the grafts probably do not reestablish normal knee biomechanics.

Menisci, fibrocartilaginous structures sitting between the femur and tibia in the medial and lateral knee compartments, distribute weight-bearing load widely throughout the knee; they also serve as spacers between the femur and the tibia so that ligaments do not become lax. Meniscal tears are a major cause of knee OA. Tears occur either acutely or chronically. Young and middle-aged persons can sustain acute tears during sports and other activities, sometimes during twisting injuries. These tears are often operated on and repaired with the meniscus partially resected. Knees that have undergone these partial meniscectomies are at high risk of later knee OA,^{25,26} and this high rate of OA has led to concerns that perhaps menisci should not be even partially removed because of the important biomechanical functions they serve. However, in a longitudinal study of persons with and without incidental meniscal tears, none of whom had undergone surgery, those with meniscal tears had a much higher risk of later knee OA²⁷ than those without such tears. Thus when the meniscus is torn (symptomatically or not), whether operated on or not, this tear markedly increases the risk of later knee OA. Chronic meniscal tears²⁸ occur in from 20% to 40% of middle-aged and older men and women and are not strongly associated with knee pain.

Thus not only are meniscal tears, even incidental ones, potent risk factors for later OA of the knee, but they are common findings. This suggests that much of the knee OA that occurs in middle-aged and older people may be a consequence of a meniscal tear. In middle-aged persons, incidental tears may occur in already degenerating meniscal tissue, and such degenerative changes may precede changes in hyaline cartilage; these changes make the meniscus highly susceptible to tears with minor injury, which then cause disease elsewhere in the joint.

Those with OA who have concurrent meniscal tears are also at high risk of experiencing disease progression.²⁹ Menisci are tethered to a variety of other structures within the joint, and when these connections get torn, menisci are extruded outside the joint margin, and the joint is essentially without a functioning meniscus. This extrusion, which can be partial or complete, is itself a major risk factor for disease progression.²⁹

Neuromuscular factors and osteoarthritis

The local joint environment includes structures outside the articular surface, including muscles and the nervous system that controls those muscles. Healthy muscles and their coordinated movements during loading, weight bearing, and joint excursion are critical to joint protection. To the extent that joints move beyond physiologic range of motion because of a tear in a ligament, joints can be put in positions in which protective mechanisms do not work optimally, and that can lead to joint injury. This could be one reason why women with hyperlaxity of the joints may be at increased risk of OA, although the effect of hyperlaxity on OA is by no means clear.³⁰ Perhaps more importantly, muscle conditioning and the spinal reflex system that coordinates muscular movement smoothly through joint excursion must function normally for the joint to be protected during use. Muscles move in a coordinated fashion thanks to nervous system organs inside periarticular muscle, ligament, and skin, which provide instantaneous spinal cord-based feedback on the position and movement of muscles across the joint and constitute the system of proprioception across the joint. Studies³¹ suggest that those with knee OA have impaired proprioception compared to those of a similar age without knee OA. Proprioception can be measured in a number of ways, which do not all provide the same physiologic information. One method is to assess a person's ability to detect trivial passive movement of the joint, and another is to evaluate a person's ability to reproduce a particular knee flexion angle after they have used their muscles to generate that flexion angle. If they cannot reproduce that flexion angle, then their proprioceptive acuity is poor. In a study of over 2000 individuals with and without knee OA,³² those who showed poor accuracy in reproducing knee flexion angle had a slightly greater functional decline and slightly worse pain than those who showed better accuracy but did not have an increased risk of incident or progressive radiographic knee OA. Measuring proprioceptive acuity is fraught with problems of poor reproducibility, and different ways of measurement can sample different physiologic phenomena only some of which may be relevant to knee OA. Thus further data are needed on the impacts on OA of different neurosensory inputs that are part of proprioceptive pathways.

In addition to coordination of muscle activity across the joint, optimal neuromuscular function should include adequate muscle strength so that muscles can stabilize the joints during activity, preventing them from moving beyond physiologic excursion limits, and contract in such a way that load is distributed broadly across the joint. In theory, a person whose muscles bridging the joint are strong should have less risk of developing knee OA and a lower risk of progression if disease is present.

Despite the conceptual appeal of invoking muscle strength as an important factor related to the development of knee OA, the results of longitudinal studies examining the relation between muscle strength and the development of knee OA have been mixed. Two large well-done studies suggest that weak quadriceps strength increases the risk of both radiographic OA³³ and joint space loss³⁴ in women but not men. Importantly, in one of these studies,³⁵ quadriceps weakness increased the risk of developing symptomatic knee OA in both sexes. The ratio of quadriceps to hamstring strength has shown no relation to the development of knee OA.³⁵ In longitudinal studies of individuals with knee OA, quadriceps weakness does not appear to predispose to radiographic progression nor to cartilage loss on MRI.^{36,37} Even prolonged strength training programs have had only a borderline effect on disease progression.³⁸ Quadriceps weakness may predispose to structural disease in the patellofemoral joint more than it does in the tibiofemoral articulation.^{39,40} Although studies examining quadriceps weakness and structural disease have generated inconsistent findings, persons who are weaker have worse pain and function in the diseased joint than those who are stronger.^{33,41} This relationship is present even when those who have pain during the muscle strength examinations are excluded.⁴²

Muscle strength or function may contribute to disease in the knee in other ways. Strong hip external rotators and abductors can alter the position of the knee during walking and thereby affect knee mechanics and influence the development or progression of knee OA. In fact, weakness of muscles surrounding the hip exists in persons with knee OA,⁴³ but it is not clear if this weakness is causal. Also, obese persons at high risk of knee OA often have higher muscle mass and strength than thinner persons at lower risk of OA. However, these obese persons may have weakness relative to the amount of muscle mass (so-called muscle-specific torque) and that may predispose them to OA.⁴⁴
